Abstract

We discuss an integer linear programming modeling system based on relational algebra. In this system, all modeling related activities, such as model formulation, model instantiation, and model and instance management, are done using simple operations such as selection, projection, and predicated join.

1 Introduction

Anyone who has ever attempted to apply mathematical programming in practice knows that it is usually not a simple and straightforward exercise. The road from a real-life problem situation to a satisfactory solution can be quite long and full of complications. There are many factors that contribute to this, but one of the most important is the large amount of data that needs to be handled.

Since it is standard practice in industry to store information in databases, Mitra et al. [MKLM95] argue that in order for mathematical programming to gain better acceptance as a modeling tool within corporate decision studies, a unified approach which integrates a modeling language with a relational database is necessary, as it will provide a more powerful tool for constructing models which are truly data driven. They propose to achieve this by incorporating relational database structures into the syntax of the algebraic modeling language MPL [Max93].

The goal of our research has been to design an integrated modeling environment in which data management plays an even more central role and in which all modeling activities, such as model formulation, model instantiation, model solution, model validation, and solution analysis, are done in a common paradigm. Our efforts have resulted in a modeling environment based on relational algebra. Model formulation, instance generation, and solution manipulation are all done using relational operators such as selection, projection, and join. Many other desirable features of modeling environments, such as model management, instance management, and report writing are facilitated because they can be done using available relational database tools. Furthermore, model builder as well as end-user can work with the same system and users can easily share models. A prototype has been implemented to provide a ‘proof of concept’. The prototype demonstrates that it is possible to develop a modeling environment for mathematical programming using a single paradigm: relational algebra.
Several other researchers have observed the potential of relational algebra for mathematical programming modeling. Our research was partly motivated by the ideas presented by Johnson [Joh89]. Choobineh [Cho91] designed SQLMP, an extension of SQL (Structured Query Language) [ANS, Dat87] for mathematical programming that uses the algebraic paradigm for model conceptualization. We do not extend SQL and use the block-schematic paradigm for model conceptualization. The block-schematic paradigm is described by Baker [Bak83] and Welch [Wel87] and forms the basis of MathPro [Mat89] and MIMI [Bak92]. The reason we use the block-schematic paradigm is purely pragmatic; the block-schematic approach is easier to embed in a relational modeling scheme. We are not claiming that the block-schematic paradigm is better than the algebraic approach used in systems such as GAMS [BKM88], AMPL [FGK93], MPL [Max93], and AIMMS [BE93]. Which approach to use is largely a matter of taste, although it is claimed that many industrial users, particularly those in the process industry, prefer the block-schematic paradigm as it is closer to their "activity-based" view of the model. One disadvantage of the block-schematic paradigm is that it is mainly appropriate for linear optimization models. Dolk [Dol88] shows how structured models (as introduced by Geoffrion [Geo87]) can be represented and manipulated easily using SQL. Dolk also discusses how SQL might be used to facilitate the solution of mathematical programming models. He expects that this will require nonstandard SQL features. Our research shows that interfacing with an optimizer can be done completely with the tools used to access a relational database system. By using a standard interface language like SQL, the interface can be represented in a database-independent way, with some minor exceptions.

The paper is organized as follows. In Section 2, we present our view on the characteristics of good modeling environments. In Section 3, we give a brief introduction to relational operators. In Section 4, we introduce the basic concepts of relational modeling. In Section 5, we show how to use these basic concepts to model the fleet assignment problem. In Section 6, we illustrate how these concepts can be implemented in a standard
database environment. In Section 7, we present some conclusions. In the appendices, we give relational models for several well-known planning problems and an overview of the functionality of our prototype.

2 Modeling environments

A model is an abstraction of a real-life decision situation. Therefore, its solution has to be interpreted with care and not as the definitive answer to the real-life problem.

The process of generating a satisfactory solution to a real-life problem involves developing a model (which typically means making simplifying assumptions), generating an instance of the model (which typically involves gathering huge amounts of data), solving the instance (which typically involves transforming the instance data into a machine readable form), validating the solution and the model (which involves verifying the appropriateness of the simplifying assumptions), and, if the need arises, repeating these steps. In addition, models may have to be modified when changes occur in the real-life decision situation or user needs become different. This iterative process represents the modeling life cycle in which a model evolves over time.

A computer based linear programming modeling environment has to nurture the entire modeling life cycle. Such a system must facilitate the ongoing evolution of models and support the management of resources used in the modeling life cycle, such as data, models, solvers, solutions.

Nowadays, highly accurate data gathering and processing technologies are widely available in industry. Typically, the availability of more and more accurate data leads to the development of more detailed models, which means that data management facilities in modeling environments are crucially important. Most of the data required for an instance of a model will be stored in corporate databases and has to be processed before it can be used to construct an instance of the model at hand.
Typically, it is necessary to solve many instances of one model with varying data. Therefore, it is important that data and model are separated, i.e., the model should be stated independently from any data. Consequently, a modeling environment should support, if not enforce, the separation of model and instance.

These are only a few, though very important, features that an effective modeling environment should have. Other desirable features include support for model documentation and report writing, and the availability of different views, such as lists, schemas, figures, and charts, of the model, the instance data, and the solution. The modeling concepts we propose are well suited to form the basis of a modeling system that has these desired features.

3 Relational operators

The relational modeling system we propose makes frequent use of the relational operators selection, projection, and predicated join. Relational operators are part of relational algebra and formally operate on relations. However, for presentational convince, we think of a relation as a table (as is done in relational databases), and discuss these relational operators in terms of how they operate on tables. The selection operator constructs a new table by taking a horizontal subset of an existing table. The projection operator constructs a new table by taking a vertical subset of an existing table. The predicated join operator constructs a new table from two existing tables. Each row in the resulting table is formed by concatenating two rows, one from each of the original tables. Rows in the resulting table that do not satisfy the condition (or predicate) are eliminated.

SQL is the most popular data manipulation language that implements these operators. SQL statements have a natural and intuitive interpretation, and we will use SQL to present the concepts of our relational modeling system. We briefly introduce the SQL
statements used in the design and implementation of our relational modeling system. For more detailed explanations on SQL we refer the reader to [Dat87, EN94].

The **CREATE TABLE** statement is used to define and create a relational data table.

```
CREATE TABLE table (attribute attribute_type, ..., attribute attribute_type);
```

**Examples:**

```
CREATE TABLE production (plant CHAR(10), product CHAR(10), capacity NUMBER, cost NUMBER);
CREATE TABLE demand (center CHAR(10), product CHAR(10), amount NUMBER);
```

The fundamental operation in SQL is the *mapping*, represented syntactically as **SELECT-FROM-WHERE**. The mapping operation is effectively a horizontal subsetting (selection operator) followed by a vertical subsetting (projection operator). If the mapping operates on two tables, a predicated join is performed before the horizontal and vertical subsetting. More formally, a query to the database is formulated as follows:

```
SELECT attribute(s)
FROM table(s)
WHERE predicate(s)
```

In SQL each query is evaluated as follows. First the cartesian product of the tables in the **FROM** clause is computed. Then the result is filtered by the predicate(s) of the **WHERE** clause. The last step is the display of the results which were requested through the **SELECT** clause.

**Example:**

```
SELECT plant, center
FROM production, demand
WHERE production.product = demand.product
```
An extension to this basic query is obtained by using the GROUP BY operator. The GROUP BY operator rearranges the FROM table into partitions or groups. Within any one group all rows have the same value for the GROUP BY field. The SELECT clause is then applied to each group of the partitioned table rather than to each row of the original table.

Example:

```sql
SELECT product, SUM(amount)
FROM demand
GROUP BY product;
```

The last SQL construct used in the design and implementation of our relational modeling system is the view. A view is simply a particular look at the database. Although a view is a table, it does not exist physically in the database as a table; no storage space or data are allocated for it. The CREATE VIEW statement is used to define a virtual table.

Example:

```sql
CREATE VIEW largecap (plant, product, capacity) AS
SELECT plant, product, capacity
FROM production
WHERE capacity > 1000;
```

4 Relational modeling

We will illustrate the basic concepts of relational modeling by means of an example. We consider a production distribution problem with single sourcing requirements [MWJS78].

4.1 Problem situation

The problem is to decide how much of each product to produce at plants, how to ship to warehouses, and transship to demand-centers subject to the constraint that a warehouse
has to ship all of the demand for all products to any demand-center to which it ships. In other words, each demand-center is assigned a single warehouse that must meet all of its demand for the several products.

4.2 Instance data

The data involved in this model are production cost per product per plant, production capacity per product per plant, shipping cost from plant to warehouse, shipping cost from warehouse to demand center, and demand per product per demand center. These data are assumed to be available in a database in user data tables: Production, Shipcost, Tranship, and Demand. An instance of the production-distribution problem is given by the following user data tables. This instance will be used throughout our discussion of the basic concepts of our approach.

Table Production:

<table>
<thead>
<tr>
<th>PLANT</th>
<th>PRODUCT</th>
<th>CAPACITY</th>
<th>COST</th>
</tr>
</thead>
<tbody>
<tr>
<td>topeka</td>
<td>chips</td>
<td>200</td>
<td>230</td>
</tr>
<tr>
<td>topeka</td>
<td>nachos</td>
<td>800</td>
<td>280</td>
</tr>
<tr>
<td>newyork</td>
<td>chips</td>
<td>600</td>
<td>255</td>
</tr>
</tbody>
</table>

Table Shipcost:

<table>
<thead>
<tr>
<th>PLANT</th>
<th>WHSE</th>
<th>COST</th>
</tr>
</thead>
<tbody>
<tr>
<td>topeka</td>
<td>topeka</td>
<td>1</td>
</tr>
<tr>
<td>topeka</td>
<td>newyork</td>
<td>45</td>
</tr>
<tr>
<td>newyork</td>
<td>topeka</td>
<td>45</td>
</tr>
<tr>
<td>newyork</td>
<td>newyork</td>
<td>2</td>
</tr>
</tbody>
</table>

Table Tranship:

<table>
<thead>
<tr>
<th>WHSE</th>
<th>CENTER</th>
<th>COST</th>
</tr>
</thead>
<tbody>
<tr>
<td>topeka</td>
<td>east</td>
<td>60</td>
</tr>
<tr>
<td>topeka</td>
<td>south</td>
<td>30</td>
</tr>
<tr>
<td>topeka</td>
<td>west</td>
<td>40</td>
</tr>
<tr>
<td>newyork</td>
<td>east</td>
<td>10</td>
</tr>
<tr>
<td>newyork</td>
<td>south</td>
<td>30</td>
</tr>
<tr>
<td>newyork</td>
<td>west</td>
<td>80</td>
</tr>
</tbody>
</table>

Table Demand:

<table>
<thead>
<tr>
<th>CENTER</th>
<th>PRODUCT</th>
<th>AMOUNT</th>
</tr>
</thead>
<tbody>
<tr>
<td>east</td>
<td>chips</td>
<td>200</td>
</tr>
<tr>
<td>east</td>
<td>nachos</td>
<td>50</td>
</tr>
<tr>
<td>south</td>
<td>chips</td>
<td>250</td>
</tr>
<tr>
<td>south</td>
<td>nachos</td>
<td>180</td>
</tr>
<tr>
<td>west</td>
<td>chips</td>
<td>150</td>
</tr>
<tr>
<td>west</td>
<td>nachos</td>
<td>300</td>
</tr>
</tbody>
</table>
4.3 Column and row strips

In an integer linear program, activities or decisions are modeled as variables, possibly with integrality restrictions on some of them, and restrictions and relations among the decisions are modeled as linear equations and inequalities in terms of the variables. Typically, variables in an integer linear program can be grouped into classes with similar characteristics, based on what they represent in the underlying problem situation. Similarly, the linear equations and inequalities, or constraints, can also be grouped into classes with similar characteristics. These classes of variables and classes of constraints can be used to construct a block-schematic view of the integer linear program, see for instance Welch [Wel87]. In a block-schematic view, classes of variables are called column strips, classes of constraints are called row strips, and their intersections, where interactions occur, are called blocks.

There are three types of decisions (classes of variables) in our production distribution model:

- How much to produce of each product at a plant?
- How much of each product to ship from a plant to a warehouse?
- Which warehouse to assign to each center?

Each type of decision will be represented by a class of variables in the model and by a column strip in the block-schematic representation. Since there are three types of decisions, there will be three column strips: Produce, Ship, and Assign.

Since each decision is related to a specific subset of the data, e.g., we have to determine how much to produce for each combination of a plant and a product, we can think of column strips as selections of data, and we can thus define them using the SQL construct of a view.
Ultimately, a modeling system has to prepare a machine readable form of an instance for an optimizer. Therefore, any modeling system has to create a representation of the coefficient matrix that is understood by the optimizer. This is typically done in the form of triplets, one for each nonzero coefficient, consisting of a column (or variable) index, a row (or constraint) index, and the value of the coefficient. To accommodate the generation of such a representation, we store an index with each variable and each constraint.

Since the relational database paradigm does not impose an ordering on the rows of a table, it is nontrivial to create such an index. Fortunately, most commercial implementations of SQL provide a pseudo-column which contains a number indicating the sequence in which a row was selected and we will make use of this pseudo-column to create our index. In Oracle this pseudo-column is called `RowNum`, in Informix it is called `RowId`, whereas in Microsoft Access it is called `AutoNumber`. Since this is not a standard SQL feature and different vendors use different names for this feature, our relational modeling system has to be adapted depending on the database management system used for the implementation. In the remainder we assume that we are working with Oracle and use the `RowNum` feature to define the unique indices for each row and column strip.

Throughout the paper, we carry the indices in the tables explicitly, since they are important to convey the underlying concepts of our relational modeling system. However, in a commercial implementation based on the relational concepts we present, these indices can be hidden from the user since their generation and manipulation can be done automatically.

```sql
CREATE VIEW Produce (ix, plant, product) AS
SELECT RowNum, plant, product
FROM Production;

CREATE VIEW Ship (ix, plant, whse, product) AS
SELECT RowNum, plant, whse, product
```
FROM Production, Shipcost
WHERE Production.plant = Shipcost.plant;

CREATE VIEW Assign (ix, whse, center) AS
SELECT RowNum, whse, center
FROM Tranship;

The definition of Ship, for example, indicates that there will be a variable for each combination of a plant, a warehouse, and a product and that these combinations can be obtained from the user data tables Production and Shipcost. Based on the data tables of the instance specified above, the column strip Ship defines the following variables plus associated indices.

<table>
<thead>
<tr>
<th>IX</th>
<th>PLANT</th>
<th>WHSE</th>
<th>PRODUCT</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>topeka</td>
<td>topeka</td>
<td>chips</td>
</tr>
<tr>
<td>2</td>
<td>topeka</td>
<td>newyork</td>
<td>chips</td>
</tr>
<tr>
<td>3</td>
<td>topeka</td>
<td>topeka</td>
<td>nachos</td>
</tr>
<tr>
<td>4</td>
<td>topeka</td>
<td>newyork</td>
<td>nachos</td>
</tr>
<tr>
<td>5</td>
<td>newyork</td>
<td>topeka</td>
<td>chips</td>
</tr>
<tr>
<td>6</td>
<td>newyork</td>
<td>newyork</td>
<td>chips</td>
</tr>
</tbody>
</table>

Similarly, there are three types of relations and restrictions in the model.

- Production at a plant is linked to shipping from the plant to a warehouse, i.e., everything that is produced should be shipped to some warehouse.

- Enforcement of the product flow balance, i.e., the total amount of a product shipped from plants to a warehouse should equal the total amount of a product shipped to the centers.

- Enforcement of the single sourcing requirement, i.e., each center receives all its demand from a single warehouse.
Each class of constraints will be represented by a row strip in the block-schematic representation. Since there are three classes of constraints, there will be three row strips: Prodrow, Shiprow, and Centrow.

CREATE VIEW Prodrow (ix, plant, product) AS
SELECT RowNum, plant, product
FROM Production;

CREATE VIEW Shiprow (ix, whse, product) AS
SELECT RowNum, whse, product
FROM Tranship, Demand
WHERE Tranship.center = Demand.center
GROUP BY whse, product;

CREATE VIEW Centrow (ix, center) AS
SELECT RowNum, center
FROM Demand;

Based on the data tables of the instance specified above, the row strip ShipRow defines the following constraints plus associated indices.

<table>
<thead>
<tr>
<th>IX</th>
<th>WAREHOUSE</th>
<th>PRODUCT</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>topeka</td>
<td>chips</td>
</tr>
<tr>
<td>2</td>
<td>topeka</td>
<td>nachos</td>
</tr>
<tr>
<td>3</td>
<td>newyork</td>
<td>chips</td>
</tr>
<tr>
<td>4</td>
<td>newyork</td>
<td>nachos</td>
</tr>
</tbody>
</table>

Observe that we do not specify the number of variables in a class or the number of constraints in a class. The size of an instance is not part of the model, but determined automatically by the number of records in the user data tables.
4.4 Blocks

So far we have defined the column strips and row strips of the matrix, i.e., the classes of variables and the classes of constraints of the model. Next, we have to determine whether a class of variables interacts with a class of constraints, i.e., whether there are nonzero entries in the block defined by the associated column and row strips. This gives the blocks with the technological coefficients of the matrix.

CREATE VIEW Block11 (rowix, colix, coef) AS
SELECT Prodrow.ix, Produce.ix, -1
FROM Prodrow, Produce
WHERE Prodrow.product = Produce.product
AND Prodrow.plant = Produce.plant;

CREATE VIEW Block12 (rowix, colix, coef) AS
SELECT Prodrow.ix, Ship.ix, 1
FROM Prodrow, Ship
WHERE Prodrow.product = Ship.product
AND Prodrow.plant = Produce.plant;

CREATE VIEW Block22 (rowix, colix, coef) AS
SELECT Shiprow.ix, Ship.ix, -1
FROM Shiprow, Ship
WHERE Shiprow.product = Ship.product
AND Shiprow.whse = Ship.whse;

CREATE VIEW Block23 (rowix, colix, coef) AS
SELECT Shiprow.ix, Assign.ix, amount
FROM Shiprow, Assign, Demand
WHERE Shiprow.product = Demand.product
AND Shiprow.whse = Assign.whse
AND Assign.center = Demand.center;

CREATE VIEW Block33 (rowix, colix, coef) AS
SELECT Centrow.ix, Assign.ix, 1
FROM Centrow, Assign
WHERE Centrow.center = Assign.center;

The definition of Block23, for example, indicates that there will be a nonzero coefficient for each product that is shipped from a warehouse to a demand center and that the value of this coefficient is equal to the demand at this demand center, which can be found in the user data table Demand.

As an example, we show the intermediate table that is implicitly generated during the construction of the virtual table Block23 just before the final selection of rowix, colix, and coef is made.

<table>
<thead>
<tr>
<th>WHSE</th>
<th>PRODUCT</th>
<th>CENTER</th>
<th>CDEF</th>
<th>COLIX</th>
<th>ROWIX</th>
</tr>
</thead>
<tbody>
<tr>
<td>topeka</td>
<td>chips</td>
<td>east</td>
<td>200</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>topeka</td>
<td>chips</td>
<td>south</td>
<td>250</td>
<td>2</td>
<td>1</td>
</tr>
<tr>
<td>topeka</td>
<td>chips</td>
<td>west</td>
<td>150</td>
<td>3</td>
<td>1</td>
</tr>
<tr>
<td>topeka</td>
<td>nachos</td>
<td>east</td>
<td>50</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>topeka</td>
<td>nachos</td>
<td>south</td>
<td>180</td>
<td>2</td>
<td>2</td>
</tr>
<tr>
<td>topeka</td>
<td>nachos</td>
<td>west</td>
<td>300</td>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>newyork</td>
<td>chips</td>
<td>east</td>
<td>200</td>
<td>4</td>
<td>3</td>
</tr>
<tr>
<td>newyork</td>
<td>chips</td>
<td>south</td>
<td>250</td>
<td>5</td>
<td>3</td>
</tr>
<tr>
<td>newyork</td>
<td>chips</td>
<td>west</td>
<td>150</td>
<td>6</td>
<td>3</td>
</tr>
<tr>
<td>newyork</td>
<td>nachos</td>
<td>east</td>
<td>50</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td>newyork</td>
<td>nachos</td>
<td>south</td>
<td>180</td>
<td>5</td>
<td>4</td>
</tr>
<tr>
<td>newyork</td>
<td>nachos</td>
<td>west</td>
<td>300</td>
<td>6</td>
<td>4</td>
</tr>
</tbody>
</table>

Observe that each block defines a set of triplets specifying the nonzero coefficients of that block, and that all triplets are specified relative to that block. Therefore, to specify the complete matrix all we have to do is impose an ordering on the column strips and row strips and add the appropriate offsets to the row and column indices appearing in the triplets.
It is convenient for us to consider information pertaining purely to a class of variables, such as objective coefficients, lower, and upper bounds, and information pertaining purely to a class of constraints, such as lower and upper bounds, as blocks as well. Since this type of information is typically referred to as belonging to the rim of the matrix, we will sometimes refer to these blocks as *rim blocks*. Note that we specify constraints using lower and upper bounds on the activity instead of using a sense and a right-hand side.

Below are the definitions of the rim blocks. Since these blocks will be part of the matrix description that will be input to an integer linear programming optimizer, we create triplets.

```sql
CREATE VIEW ProduceObj (rowix, colix, coef) AS
SELECT null, ix, cost
FROM Produce, Production
WHERE Produce.plant = Production.plant
AND Produce.product = Production.product;

CREATE VIEW ShipObj (rowix, colix, coef) AS
SELECT null, ix, cost
FROM Ship, Shipcost
WHERE Ship.plant = Shipcost.plant
AND Ship.whse = Shipcost.whse;

CREATE VIEW AssignObj (rowix, colix, coef) AS
SELECT null, ix, SUM(amount) * cost
FROM Assign, Demand, Tranship
WHERE Assign.center = Tranship.center
AND Assign.whse = Tranship.whse
AND Assign.center = Demand.center
GROUP BY cost;

CREATE VIEW ProduceUp (rowix, colix, coef) AS
SELECT null, ix, cost
FROM Produce, Production
WHERE Produce.plant = Production.plant
AND Produce.product = Production.product;
```

15
SELECT ix, null, capacity
FROM Produce, Production
WHERE Produce.product = Production.product;

CREATE VIEW ProdrowLo (rowix, colix, coef) AS
SELECT ix, null, 0
FROM Prodrow;

CREATE VIEW ProdrowUp (rowix, colix, coef) AS
SELECT ix, null, 0
FROM Prodrow;

CREATE VIEW ShiprowLo (rowix, colix, coef) AS
SELECT ix, null, 0
FROM Shiprow;

CREATE VIEW ShiprowUp (rowix, colix, coef) AS
SELECT ix, null, 0
FROM Shiprow;

CREATE VIEW CentrowUp (rowix, colix, coef) AS
SELECT ix, null, 1
FROM Centrow;

CREATE VIEW CentrowLo (rowix, colix, coef) AS
SELECT ix, null, 1
FROM Centrow;

The definition of ProduceObj indicates that for each combination of a plant and a product defined in the column strip Produce, the objective coefficient can be found in the Production user data table in the field COST of the row that matches this particular combination. The definition of AssignObj shows that it is also possible to have computed objective coefficients. This completes the model description. A block-schematic view of the model is given in Figure 1.
Observe that the definition of column strips, row strips, and blocks only depends on the structure of the user data tables, not on the records contained in those tables. This ensures complete separation of model and data. It also means that the same model definition can handle instances with two plants, two products, two warehouses, and three demand centers, as well as instances with hundreds of plants, thousands of products, hundreds of warehouses, and millions of demand centers. Observe that an instance of a model exists as a collection of views, i.e., virtual tables. This is a major difference from systems in which instances are physically stored in a database.

In defining the column strips, row strips, and blocks of the production distribution model, we have presented the required SQL statements in full detail. This was done to convey how a relational modeling system can be implemented. However, a lot of information contained in the SQL statements does not pertain to the model, but is a result of the SQL syntax. In any commercial implementation of a modeling environment based on relational modeling concepts, a user interface needs to be developed that shields a user from the underlying SQL syntax and indexing, reducing the effort required to specify a model. In such a system, the user would specify a block simply by using the names of the column and row strips and the corresponding relationship between the attributes of the strips. The actual detailed SQL queries would be created automatically by the system.

Figure 1: Block schematic view of the production-distribution model
4.5 Ordered domains

An important class of linear programming models involves multi-period production planning. Such models typically contain a class of balancing constraints that ensure a proper transition from one period to the next, e.g., for every period except the first, the inventory at the start of period $t - 1$ plus the production in period $t - 1$ minus the sales in period $t - 1$ has to equal the inventory at the start of period $t$. Such models pose a serious problem for the relational modeling approach because it relies on a natural ordering of the data, such as weeks, months, and years.

The relational model that forms the basis of relational database implementations does not support the concept of ordered domains. There are two ways to deal with this dilemma. First, commercial implementations of a relational database have special functions related to time and we could make use of these. Second, when building a model, we can use numerical representations of the ordered domains and use SQL constructs to implement ordering concepts such as ‘first’, ‘successor’, and ‘predecessor’.

As an example consider the following two user data tables. The first table is not necessary, but mainly serves as a table that can be used in the report generation phase.

**Table Date:**

<table>
<thead>
<tr>
<th>NAME</th>
<th>PERIOD</th>
</tr>
</thead>
<tbody>
<tr>
<td>February</td>
<td>2</td>
</tr>
<tr>
<td>April</td>
<td>4</td>
</tr>
<tr>
<td>June</td>
<td>6</td>
</tr>
</tbody>
</table>

**Table Production:**

<table>
<thead>
<tr>
<th>PRODUCT</th>
<th>PERIOD</th>
<th>CAPACITY</th>
<th>COST</th>
</tr>
</thead>
<tbody>
<tr>
<td>chips</td>
<td>2</td>
<td>2000</td>
<td>76</td>
</tr>
</tbody>
</table>
Consider the class of balancing constraints mentioned above. The column strip associated with the inventory variables can be defined as

```sql
CREATE VIEW Inventory (ix, product, period) AS
SELECT RowNum, product, period
FROM production;
```

We require a balance constraint for each product in each period except for the first. The row strip associated with the balancing constraints can be defined as

```sql
CREATE VIEW Balance (ix, product, period) AS
SELECT RowNum, product, period
FROM production
WHERE period > (SELECT min(period) FROM production);
```

We have used a subquery to determine the first period appearing in the table production. For this class of constraints, there are two interactions between the column strip and the row strip – there is product flow “into” the period and “out” of the period. To accomplish this, we simply define the two matrix blocks

```sql
CREATE VIEW Block_1 (rowix, colix, coef) AS
SELECT Balance.ix, Inventory.ix, -1
FROM Balance, Inventory
WHERE Balance.product = Inventory.product
AND Balance.period = Inventory.period;

CREATE VIEW Block_2 (rowix, colix, coef) AS
```

```sql
```
SELECT Balance.ix, Inventory.ix, 1
FROM Balance, Inventory
WHERE Balance.product = Inventory.product
AND Inventory.period =
    (SELECT max(period) FROM Inventory WHERE period < Balance.period);

Again, we have used a subquery, this time to determine the previous period appearing in
the production table. This concludes our description of the basic concepts of relational
modeling. In Appendix A, we provide examples of relational models for some well-known
planning problems.

5 The Fleet Assignment Problem

To provide the reader with a real-life application in which using the relational modeling
scheme is a natural and convenient choice, we discuss an important planning problem
faced by the airline companies. In the fleet assignment problem, we are given a flight
schedule and a set of fleet (aircraft) types. The problem is to find a minimum cost
assignment of the fleet types to the flight legs in the schedule (see Abara [A89] for a
discussion and overview of the fleet assignment problem). The flight schedule (time
table) of a medium to large airline is huge and typically stored in a relational database.
Below we show some of the typical information found in the database.

Table Schedule:

<table>
<thead>
<tr>
<th>LEG</th>
<th>DEPSTA</th>
<th>DEPTIM</th>
<th>ARRSA</th>
<th>ARRTIM</th>
<th>FLEET</th>
<th>COST</th>
</tr>
</thead>
<tbody>
<tr>
<td>101</td>
<td>DFW</td>
<td>745</td>
<td>BOS</td>
<td>1055</td>
<td>734</td>
<td>8270</td>
</tr>
<tr>
<td>101</td>
<td>DFW</td>
<td>745</td>
<td>BOS</td>
<td>1055</td>
<td>757</td>
<td>11088</td>
</tr>
<tr>
<td>101</td>
<td>DFW</td>
<td>745</td>
<td>BOS</td>
<td>1055</td>
<td>767</td>
<td>12098</td>
</tr>
<tr>
<td>102</td>
<td>BOS</td>
<td>1200</td>
<td>DFW</td>
<td>1500</td>
<td>734</td>
<td>8270</td>
</tr>
<tr>
<td>102</td>
<td>BOS</td>
<td>1200</td>
<td>DFW</td>
<td>1500</td>
<td>757</td>
<td>11088</td>
</tr>
</tbody>
</table>
In this particular example, we see that there is flight from Dallas/Fort Worth International Airport to Logan Airport in Boston departing at 7:45AM and arriving at 10:55AM and that this flight can be flown by either a Boeing 734 at a cost of 8270, a Boeing 737 at a cost of 9198, a Boeing 757 at a cost of 11088, or a Boeing 767 at a cost of 12098.

The information on available fleet types is also stored in a relational database and looks somewhat like this

Table Fleets:

<table>
<thead>
<tr>
<th>FLEET</th>
<th>AVAIL</th>
</tr>
</thead>
<tbody>
<tr>
<td>734</td>
<td>6</td>
</tr>
<tr>
<td>757</td>
<td>2</td>
</tr>
<tr>
<td>767</td>
<td>9</td>
</tr>
</tbody>
</table>

A feasible fleet assignment must assign a fleet type to each flight leg, cannot use more aircrafts of a given fleet type than are available, and must ensure that aircrafts that arrive at a station either depart or stay on the ground and similarly that aircrafts depart from a station where they landed earlier.

To model the fleet assignment problem, we introduce two classes of variables. First, a class of binary variables indicating for each combination of flight leg and fleet type whether or not the fleet type is assigned to the flight leg. Second, a class of integer variables counting the number of aircrafts of a specific fleet type on the ground at a particular station and time.

CREATE VIEW Assign (ix, leg, fleet) AS
SELECT RowNum, leg, fleet
FROM Schedule;

CREATE VIEW GroundArc (ix, fleet, station, time) AS
SELECT RowNum, Fleets.fleet, arrsta, arrtime
FROM Fleets, Schedule
UNION
SELECT RowNum, Fleets.fleet, depsta, deptime
FROM Fleets, Schedule;

Note that we create a so-called *ground arc* for each fleet type at each station and each event (arrival or departure) at that station. Ground arcs, as the name suggests are used to model aircrafts that stay on the ground at a station.

There are three classes of constraints. First, which is at the heart of the problem, we have ensure that each flight leg is assigned exactly one fleet type.

CREATE VIEW Cover (ix, leg) AS
SELECT RowNum, leg
FROM Schedule
GROUP BY leg;

Second, we have to ensure that the fleet assignments are consistent, in the sense that there is flow balance for each fleet type at each station and each event occurring at that station. That is to say that for each fleet type, the number of aircrafts of that fleet type “arriving” at a station (either via an incoming flight leg or via a ground arc) is equal to the number of aircrafts “departing” from the station (either via an outgoing flight leg or a ground arc).

CREATE VIEW Balance (ix, fleet, station, time) AS
SELECT ALL
FROM GroundArc;
Finally, we have to ensure for each fleet type that we do not use more aircrafts than there are available.

```
CREATE VIEW AircraftCount (ix, fleet) AS
SELECT RowNum, fleet
FROM Fleets;
```

Now we define the blocks of the matrix. Since we have to assign exactly one fleet type to each flight leg we have the following block

```
CREATE VIEW CoverBlock (rowix, colix, coef) AS
SELECT Cover.ix, Assign.ix, 1
FROM Cover, Assign
WHERE Cover.leg = Assign.leg;
```

Next, we consider the blocks that define the flow balance constraints for each fleet type at each event occurring at a station. This involves selecting appropriate incoming and outgoing arcs. We create a block handling the outgoing flight legs first.

```
CREATE VIEW BalanceAssignDep (rowix, colix, coef) AS
SELECT Balance.ix, Assign.ix, 1
FROM Balance, Assign
WHERE Assign.leg = SELECT leg FROM Schedule
    WHERE Balance.fleet = Schedule.fleet
    AND Balance.station = Schedule.depsta
    AND Balance.time = Schedule.deptime;
```

Next, we create a block handling the incoming flight legs.

```
CREATE VIEW BalanceAssignArr (rowix, colix, coef) AS
SELECT Balance.ix, Assign.ix, -1
FROM Balance, Assign
```

23
WHERE Assign.leg = SELECT leg FROM Schedule
  WHERE Balance.fleet = Schedule.fleet
  AND Balance.station = Schedule.arrsta
  AND Balance.time = Schedule.arrtime;

Now, we switch to ground arcs and start with outgoing ground arcs.

CREATE VIEW BalanceGroundOut (rowix, colix, coef) AS
SELECT Balance.ix, Ground.ix, 1
FROM Balance, Ground
WHERE Balance.fleet = Ground.fleet
AND Balance.station = Ground.station
AND Balance.time = Ground.time;

We follow with the incoming ground arcs. Selecting the incoming arcs is a bit more involved, since it requires the identification of the previous event at a station, which is done by means of a subquery. Furthermore, we need to distinguish the first event at a station from the other events, since the previous event of the first event actually occurs as the last event occurring (of the previous day).

CREATE VIEW BalanceGroundIn (rowix, colix, coef) AS
SELECT Balance.ix, Ground.ix, -1
FROM Balance, Ground
WHERE Balance.fleet = Ground.fleet
AND Balance.station = Ground.station
AND Ground.time =
  SELECT max(Ground.time) FROM Ground
  WHERE Balance.fleet = Ground.fleet
  AND Balance.station = Ground.station
  AND Ground.time < Balance.time;

CREATE VIEW BalanceGroundInFirst (rowix, colix, coef) AS
SELECT Balance.ix, Ground.ix, -1
FROM Balance, Ground
WHERE Balance.fleet = Ground.fleet
AND Balance.station = Ground.station
AND (Balance.time =
    SELECT min(Balance.time) FROM Balance
    WHERE Balance.fleet = Ground.fleet
    AND Balance.station = Ground.station)
AND Ground.time =
    SELECT max(Ground.time) FROM Ground
    WHERE Balance.fleet = Ground.fleet
    AND Balance.station = Ground.station;

To ensure for each fleet type that we do not use more aircrafts than there are available, we take a snapshot at midnight and count all the aircrafts of a specific fleet type. Since the balancing constraints ensure that the flow is a circulation the number of aircrafts in use will be the same throughout the day and taking a snapshot at midnight suffices. There are two blocks: one to account for the ‘red eye’ flights, i.e., flight legs corresponding to flights that are in the air at midnight, and one for the ground arcs that cross midnight.

CREATE VIEW RedEyeCount (rowix, colix, coef) AS
SELECT PCount.ix, Assign.ix, 1
FROM PCount, Assign
WHERE PCount.fleet = Assign.fleet
AND Assign.leg = SELECT leg FROM Schedule
    WHERE Schedule.arrtime < Schedule.deptime;

CREATE VIEW GroundCount (rowix, colix, coef) AS
SELECT PCount.ix, Ground.ix, 1
FROM PCount, Ground
WHERE PCount.fleet = Ground.fleet
AND (Ground.station, Ground.time) IN
    SELECT station, MAX(time) FROM Ground
GROUP BY station;

Specifying the rim blocks, i.e., objective function coefficients and lower and upper bounds on variables and constraints is straightforward.

6 A Relational Modeling System

The preceding sections have shown the conceptual viability of modeling linear and integer programs using a relational scheme. In this section, we describe the design of a modeling environment that supports the relational modeling paradigm. More specifically, we show how to implement model management, instance management, and solver management using relational database tools. These management tasks are performed by the modeling environment and typically invisible to a user of the system.

6.1 Model Management

In the block schematic approach, a mathematical programming model is specified entirely in terms of row strips, column strips, and matrix blocks. In a relational database environment we can conveniently manage this information for many models. We create four “system” tables: SysModels, SysRows, SysCols, and SysBlocks that contain all the information about the views defining the various models.

The SysModels table contains the names of the models present in the system. It has attributes Model and ObjSense. The Model attribute is the unique name of a model and the ObjSense attribute is MAX or MIN indicating whether the specified model is a maximization or minimization problem.

The SysRows table contains the names of the row strips present in the system. It has attributes Model and RowStrip. The Model attribute is the unique name of a model and the RowStrip attribute is the unique name of a view defining a row strip of the specified model.
The **SysCols** table contains the names of the column strips present in the system. It has attributes **Model**, **RowStrip**, and **Type**. The **Model** attribute is the unique name of a model, the **ColStrip** attribute is the unique name of a view defining a column strip of the specified model, and the **Type** attribute is CONTINUOUS, BINARY, or INTEGER indicating the variable type associated with the specified column strip.

The **SysBlocks** table contains the names of the blocks present in the system. It has attributes **Model**, **Block**, **RowStrip**, **ColStrip**, and **Type**. The **Model** attribute is the unique name of a model, the **Block** attribute is the unique name of a matrix block of the specified model, the **RowStrip** attribute is the unique name of the view defining the row strip associated with the specified block, the **ColStrip** attribute is the unique name of the view defining the column strip associated with the specified block, and the **Type** attribute is ROWLOWER, ROWUPPER, COLOBJ, COLLOWER, COLUPPER, or BLOCKDATA indicating the type of the specified block.

The tables below show the relevant entries in the system tables pertaining to the production distribution model presented in the preceding sections.

**Table SysModels:**

<table>
<thead>
<tr>
<th>Model</th>
<th>ObjSense</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>MIN</td>
</tr>
</tbody>
</table>

**Table SysRows:**

<table>
<thead>
<tr>
<th>Model</th>
<th>RowStrip</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>Prodrow</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>Shiprow</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>Centrow</td>
</tr>
</tbody>
</table>

... ...
Table SysCols:

<table>
<thead>
<tr>
<th>Model</th>
<th>RowStrip</th>
<th>Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>Produce</td>
<td>CONTINUOUS</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>Ship</td>
<td>CONTINUOUS</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>Assign</td>
<td>BINARY</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
</tr>
</tbody>
</table>

Table SysBlocks:

<table>
<thead>
<tr>
<th>Model</th>
<th>Block</th>
<th>RowStrip</th>
<th>ColStrip</th>
<th>Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>Block11</td>

<td>Prodrow</td>
<td>ROWLOWER</td>
<td></td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
<td>...</td>
<td></td>
</tr>
</tbody>
</table>

6.2 Instance Management

In the production distribution problem used to illustrate the relational modeling scheme, we have used specific data tables in the definition of the model, e.g., Production, ShipCost, Tranship, and Demand, even though we only used the structure of these tables. It is good practice, however, to define models completely independent of its instances. To do so, we make use of another feature of SQL called a synonym. A synonym is an
alias assigned to a table or view that may thereafter be used to refer to it. For each data table required in the definition of a model, we introduce a synonym and all references to data tables are made through these synonyms. Then, to create a specific instance of a model, all that needs to be done is to update the synonyms so that they refer to the actual data tables defining the instance.

The relational database environment is well suited to manage many instances of the same model. We create two system tables: **SysDataTables** and **SysInstances**.

The **SysDataTables** table contains the names of the active user data tables for a model. It has attributes **Model**, **BaseTable**, **Syn**, and **ActiveTable**. The **Model** attribute is the unique name of a model, the **Block** attribute is the unique name of a matrix block, the **BaseTable** attribute is the unique name of a special data table, called base table, having the same structure as an instance data table required in the definition of the specified model, the **Syn** attribute is the synonym for the base table used in the model definition, and the **ActiveTable** attribute is the name of the current data table associated with the specified synonym.

As mentioned before, the definition of a model depends only on the structure of the user data tables, not on the records contained in those tables. Therefore, to completely separate model and data, we use artificial tables in the model definition. The artificial tables, which we call base tables, have the same structure as the user data tables, but will always be empty. The use of base tables also gives the system a level of error-checking. When we attempt to associate a synonym with a user specified instance data table, we can check if this table has the proper structure by comparing it to the base table associated with the synonym.

In our production distribution example, instead of using the tables **Production**, **ShipCost**, **Tranship**, and **Demand** directly in the definition of the model, we create (empty) base tables **base_Production**, **base_ShipCost**, **base_Tranship**, and **base_Demand** (with the same structure) and synonyms **syn_Production**, **syn_ShipCost**, **syn_Tranship**, **syn_Demand**.
and syn Demand (initially pointing to the base tables), and use the synonyms in the definition of the model. Then to instantiate the model, we let the synonyms point to the real data tables.

Table SysDataTables:

<table>
<thead>
<tr>
<th>Model</th>
<th>BaseTable</th>
<th>Syn</th>
<th>ActiveTable</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>base_Production</td>
<td>syn_Production</td>
<td>Production</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>base_ShipCost</td>
<td>syn_ShipCost</td>
<td>ShipCost</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>base_Tranship</td>
<td>syn_Tranship</td>
<td>Tranship</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>base_Demand</td>
<td>syn_Demand</td>
<td>Demand</td>
</tr>
</tbody>
</table>

The SysInstances table contains the names of the (user data) tables of an instance. It has attributes Model, Instance, Syn, and DataTable. The Model attribute is the unique name of a model, the Instance attribute is a unique name of an instance of the specified model, the Syn attribute is the name of a synonym used in the definition of the specified model, and the DataTable attribute is the name of the data table associated with the specified synonym in the specified instance.

Table SysInstances:

<table>
<thead>
<tr>
<th>Model</th>
<th>Instance</th>
<th>Syn</th>
<th>DataTable</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>PD_January</td>
<td>syn_Production</td>
<td>Jan_Production</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_January</td>
<td>syn_ShipCost</td>
<td>ShipCost</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_January</td>
<td>syn_Tranship</td>
<td>Tranship</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_January</td>
<td>syn_Demand</td>
<td>Jan_Demand</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_February</td>
<td>syn_Production</td>
<td>Feb_Production</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_February</td>
<td>syn_ShipCost</td>
<td>ShipCost</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_February</td>
<td>syn_Tranship</td>
<td>Tranship</td>
</tr>
<tr>
<td>Prod-Dist</td>
<td>PD_February</td>
<td>syn_Demand</td>
<td>Feb_Demand</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
<td>...</td>
</tr>
</tbody>
</table>

30
Finally, there are two system tables that contain solution information: SysRuns and SysSols. The SysRuns table has attributes Model, Instance, Solver, RunDate, RunTime, Obj, and CpuTime. The Model attribute is the unique name of a model, the Instance attribute is a unique name of an instance of the specified model, the Solver attribute indicates the solver used for the run, the RunDate attribute is the date of a particular run of the specified model for the specified instance, the RunTime attribute is the time of day that the run started, the Obj attribute is the objective function value obtained in the run, and the CpuTime attribute is the CPU time for the run.

Table SysRuns:

<table>
<thead>
<tr>
<th>MODEL</th>
<th>INSTANCE</th>
<th>SOLVER</th>
<th>RUNDATE</th>
<th>RUNTIME</th>
<th>OBJ</th>
<th>CPUTIME</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>PD_January</td>
<td>GSL</td>
<td>1/1/98</td>
<td>13:14:15</td>
<td>324130</td>
<td>00:02:14</td>
</tr>
</tbody>
</table>

The SysSols table has attributes Model, Instance, RunDate, RunTime, StripName, and TableName. The Model attribute is the unique name of a model, the Instance attribute is a unique name of an instance of the specified model, the RunDate attribute is the date of a particular run of the specified model for the specified instance, the RunTime attribute is the time of day of the run, the StripName attribute is a row or a column strip name of the specified model, and the TableName attribute is the name of the data table containing the solution information for the specified row or column strip obtained in the run.

Table SysSols:

<table>
<thead>
<tr>
<th>MODEL</th>
<th>INSTANCE</th>
<th>RUNDATE</th>
<th>RUNTIME</th>
<th>STRIPNAME</th>
<th>TABLENAME</th>
</tr>
</thead>
<tbody>
<tr>
<td>Prod-Dist</td>
<td>PD_January</td>
<td>1/1/98</td>
<td>13:14:15</td>
<td>Ship</td>
<td>sol_Ship</td>
</tr>
</tbody>
</table>
Table sol_Ship:

<table>
<thead>
<tr>
<th>PLANT</th>
<th>WHSE</th>
<th>PRODUCT</th>
<th>VALUE</th>
</tr>
</thead>
<tbody>
<tr>
<td>topeka</td>
<td>topeka</td>
<td>chips</td>
<td>200</td>
</tr>
<tr>
<td>topeka</td>
<td>newyork</td>
<td>chips</td>
<td>0</td>
</tr>
<tr>
<td>topeka</td>
<td>topeka</td>
<td>nachos</td>
<td>480</td>
</tr>
<tr>
<td>topeka</td>
<td>newyork</td>
<td>nachos</td>
<td>50</td>
</tr>
<tr>
<td>newyork</td>
<td>topeka</td>
<td>chips</td>
<td>200</td>
</tr>
<tr>
<td>newyork</td>
<td>newyork</td>
<td>chips</td>
<td>200</td>
</tr>
</tbody>
</table>

Observe that the solution is put in a collection of tables. It is also possible, and in fact very easy, to put the solution immediately into the appropriate user data tables. We have chosen for the above design because it is more flexible and puts control in the hands of the user.

When the values of the decision variables have been returned to the user data tables, SQL provides a convenient tool for viewing the results of the optimization. In particular, one can easily scan subsets of the solution which may be of interest. For example, the production facility manager in Topeka can easily determine his production requirements and the total production cost by the following two queries (where we assume that the levels of production determined by the optimizer, i.e., the values of Produce, have been put in an additional field amount in the data table Production).

```
SELECT product, amount
FROM production
WHERE plant = 'topeka';

SELECT SUM(cost*amount)
FROM production
WHERE plant = 'topeka';
```
6.3 Solver management

Another feature of the relational modeling environment that is easily incorporated is to allow users to vary solver parameters, by defining a table `SysParams` to hold these parameters.

The `SysParams` table has attributes `Solver`, `Parameter`, and `Value`. The `Solver` attribute is the name of a solver, the `Parameter` attribute is the name of a parameter that can be set for the specified solver, and `Value` is the current value of the parameter.

Table `SysParams`:

<table>
<thead>
<tr>
<th>Solver</th>
<th>Parameter</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>CPLEX</td>
<td>CPX_PARAM_CLIQUES</td>
<td>1</td>
</tr>
<tr>
<td>CPLEX</td>
<td>CPX_PARAM_NODELIM</td>
<td>1000000</td>
</tr>
<tr>
<td>OSL</td>
<td>rtolpinf</td>
<td>0.00001</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
</tr>
</tbody>
</table>

The system tables introduced above form the basis of the prototype relational modeling system `ARMOS` described in the next section. It should be noted that the system tables are created only once at the installation of the system and then used by the system as an internal database of existing models, instances, and solutions. Maintaining the system tables is a responsibility of the system, not of the user of the system.

6.4 A prototype

To demonstrate the viability of the ideas and concepts presented in the previous sections, we have developed a small prototype system called `ARMOS`, A Relational MOdeling System. `ARMOS` offers a simple user interface that is coded in Embedded SQL [Ora92] and that allows a user to list the models stored in system, to load a model, to list the instances stored in the system for the loaded model, to make an instance active, to
optimize the active instance, and to display solution values. The user can also display
the model’s matrix block structure, and view the coefficients of any particular matrix
block of an active instance. Currently, both linear and mixed integer linear programs
can be solved. **ARMOS** is built on top of the commercial software package OSL [DSV].
A brief description of its functionality can be found in Appendix B.

As mentioned above, **ARMOS** is a prototype. It provides only the most basic
functionality and it only has a simple text-based user interface. There is no dedicated
graphical editor supporting model development. Our goal in developing **ARMOS** was to
verify the viability of using the relational modeling scheme in an actual implementation.

7 Discussion

This paper provides a ‘proof of concept’ demonstration showing that it is possible to
develop a modeling environment for mathematical programming using a single para-
digm: relational algebra. We feel there are several advantages to such an approach. It
is often observed, see for example Hürliman [Hür91], that despite recent developments,
mathematical programming is still not fully exploited in practice. By designing a mod-
eling environment centered around database management systems that are widely used
in industry, we believe it is possible to make mathematical programming accessible to
a wider audience. Furthermore, it is easy to set things up in such a way that using a
model has a ‘fill-in-the-blank’ feel, where solution values are immediately imported into
the appropriate data tables. This will be very appealing to end-users, and will increase
their acceptance level. (We have all witnessed the acceptance of spread-sheet like in-
terfaces!) It has also been observed, see for example Mitra et al. [MKLM95], that the
data in corporate information systems are often regularly revised and that it is therefore
desirable that a decision making system monitors changes in instance data, notifies users
that the current solution values are out of date, and allows users, with a single command,
to update that solution values. Since in the relational modeling system we propose an instance exists only through virtual links rather than physically, this feature is naturally available.

Finally, a few words on how the proposed relational modeling system compares to other systems based on the block-schematic model building paradigm, such as MIMI [Bak92] and MathPro [Mat89]. Obviously, both MIMI and MathPro are, at the moment, far easier to use than our prototype system due to their more sophisticated graphical user interfaces. MIMI also has a much larger functionality, since it includes an expert system component for rule-based model solution. On the other hand, MIMI supports only two-dimensional tables and therefore requires a hierarchy of tables to represent high dimensional strips or blocks. Our prototype does not impose this restriction, since SQL easily handles tables with multiple fields. Furthermore, MIMI requires all relevant data to be in its own private internal database, which requires copying/transferring data from the corporate database to MIMI’s database. Since the relational modeling system is built on top of the corporate database, it eliminates the data transfers and storage duplication.

Acknowledgments

We would like to thank the area editor, the associate editor, and the referees for many helpful suggestions that significantly improved the quality and presentation of the paper.

References

Appendix A

In this appendix, we give relational models for some well-known planning problems.

The Production and Distribution Model

Here we show how the SQL commands necessary to load the production and distribution model used as working example in the preceding sections into ARMOS. The data tables describing an instance of the model are just as described in the paper.

```sql
create table base_pd_production(
    plant char(10),
    product char(10),
    capacity number,
    cost number
);

create table base_pd_shipcost(
    plant char(10),
    whse char(10),
    cost number
);

create table base_pd_tranship(
    whse char(10),
    center char(10),
    cost number
);

create table base_pd_demand(
    center char(10),
    product char(10),
    amount number
);```
create synonym syn_pd_production for base_pd_production;
create synonym syn_pd_shipcost for base_pd_shipcost;
create synonym syn_pd_tranship for base_pd_transship;
create synonym syn_pd_demand for base_pd_demand;

insert into sysmodels values ('pd', 'min');

insert into sysdata values ('pd', 'base_pd_production', 'syn_pd_production', null);
insert into sysdata values ('pd', 'base_pd_shipcost', 'syn_pd_shipcost', null);
insert into sysdata values ('pd', 'base_pd_tranship', 'syn_pd_tranship', null);
insert into sysdata values ('pd', 'base_pd_demand', 'syn_pd_demand', null);

insert into sysrows values('pd', 'pd_prodrow');
insert into sysrows values('pd', 'pd_shiprow');
insert into sysrows values('pd', 'pd_centrow');

insert into syscols values('pd', 'pd_produce', 'continuous');
insert into syscols values('pd', 'pd_ship', 'continuous');
insert into syscols values('pd', 'pd_assign', 'continuous');

insert into sysblocks values('pd', 'pd_produce_ub', null, 'pd_produce', null, 'colupper');
insert into sysblocks values('pd', 'pd_prodrow_lb', 'pd_prodrow', null, null, 'rowlower');
insert into sysblocks values('pd', 'pd_prodrow_ub', 'pd_prodrow', null, null, 'rowupper');
insert into sysblocks values('pd', 'pd_shiprow_ub', 'pd_shiprow', null, null, 'rowupper');
insert into sysblocks values('pd', 'pd_shiprow_ub', 'pd_shiprow', null, null, 'rowupper');
insert into sysblocks values('pd', 'pd_centrow_ub', 'pd_centrow', null, null, 'rowupper');
insert into sysblocks values('pd', 'pd_ship_obj', null, 'pd_ship', null, 'colobj');
insert into sysblocks values('pd', 'pd_assign_obj', null, 'pd_assign', null, 'colobj');
insert into sysblocks values('pd', 'pd_block11', 'pd_prodrow', 'pd_produce', null, 'blockdata');
insert into sysblocks values('pd', 'pd_block12', 'pd_prodrow', 'pd_ship', null, 'blockdata');
insert into sysblocks values('pd', 'pd_block22', 'pd_shiprow', 'pd_ship', null, 'blockdata');
insert into sysblocks values('pd', 'pd_block23', 'pd_shiprow', 'pd_assign', 'pd_demand', 'blockdata');
insert into sysblocks values('pd', 'pd_block33', 'pd_centrow', 'pd_assign', null, 'blockdata');

from pd_centrow, pd_assign
where pd_centrow.center = pd_assign.center;

The model definition above illustrates the use of temporary views. A temporary view has been used to create the rowstrip \texttt{pd\_shiprow}. We want a row in our constraint matrix for every \textit{unique} combination of a warehouse and a product. Due to the form of our instance data tables \texttt{tranship} and \texttt{demand}, we need the SQL construct \texttt{group by} to accomplish this results.

\begin{verbatim}
select whse, product
from tranship, demand
group by whse, product;
\end{verbatim}

\begin{verbatim}
<table>
<thead>
<tr>
<th>WHSE</th>
<th>PRODUCT</th>
</tr>
</thead>
<tbody>
<tr>
<td>new york</td>
<td>chips</td>
</tr>
<tr>
<td>new york</td>
<td>nachos</td>
</tr>
<tr>
<td>topeka</td>
<td>chips</td>
</tr>
<tr>
<td>topeka</td>
<td>nachos</td>
</tr>
</tbody>
</table>
\end{verbatim}

However, the \texttt{Rownum} construct necessary to create unique indices within a row or column strip does not work with the \texttt{group by} clause. Therefore, we create a temporary view using the select statement above and then query the temporary view with the \texttt{Rownum} construct to assign the unique indices to the rowstrip.
The Diet Problem

This example is the simple and famous diet problem from linear programming. The problem is to choose certain amounts of foods to eat to minimize the total food cost, while still meeting nutritional requirements. For further explanation, an excellent description of this problem is in [FGK93].

```sql
create table base_diet_nutr(
vitamin char(20),
n_min number,
n_max number
);

create table base_diet_food(
food char(20),
f_min number,
f_max number,
cost number
);

create table base_diet_amount(
food char(20),
vitamin char(20),
amount number
);

create synonym syn_diet_nutr for base_diet_nutr;
create synonym syn_diet_food for base_diet_food;
create synonym syn_diet_amount for base_diet_amount;

insert into sysmodels values ('diet', 'min');
```
insert into sysdata values ('diet', 'base_diet_nutr', 'syn_diet_nutr', null);
insert into sysdata values ('diet', 'base_diet_food', 'syn_diet_food', null);
insert into sysdata values ('diet', 'base_diet_amount', 'syn_diet_amount', null);

where diet_req.vitamin = syn_diet_amount.vitamin and
diet_buy.food = syn_diet_amount.food;
There is only one column strip in the model, corresponding to the decision variables of the quantities of the different foods to buy. The only constraint that these choices of food must satisfy is to meet the daily nutritional requirements, so there is also only one row strip in the model. The data tables describing an instance of the model are a table describing the minimum and maximum amounts of each vitamin that must be consumed, a table describing a minimum and maximum amount of food a person can buy, as well as its cost, and a table telling the amount of each vitamin in a specific food.

The Army Model

The Army model is a classic problem in military manpower planning. We use the version presented in Wagner [Wag75] and [GM92]. Soldiers can be enlisted for any number of periods up to a certain maximum. The decision to be made is how many soldiers to employ of each enlistment length in each year to meet a required troop strength for every year of a planning horizon in order to minimize troop costs, where the costs are subject to inflation.

```sql
create table base_army_demand_data(
    year number,
    demand number
);

create table base_army_enlist_data(
    length number,
    cost number
);

create table base_army_infl_data(
    year number,
```
create synonym syn_army_demand_data for base_army_demand_data;
create synonym syn_army_enlist_data for base_army_enlist_data;
create synonym syn_army_infl_data for base_army_infl_data;

insert into sysmodels values ('army', 'min');
insert into sysdata values ('army', 'base_army_demand_data', 'syn_army_demand_data', null);
insert into sysdata values ('army', 'base_army_enlist_data', 'syn_army_enlist_data', null);
insert into sysdata values ('army', 'base_army_infl_data', 'syn_army_infl_data', null);

insert into sysrows values ('army', 'army_demand');
insert into syscols values ('army', 'army_enlist', 'integer');

insert into sysblocks values ('army', 'army_enlist_obj', null, 'army_enlist', null, 'colobj');
insert into sysblocks values ('army', 'army_demand_lb', 'army_demand', null, null, 'rowlower');
insert into sysblocks values ('army', 'army_block11', 'army_demand', 'army_enlist', null, 'blockdata');

rem ############
rem COLUMN VIEWS
rem ############

create view army_enlist(ix, year, length) as
select rownum, year, length
from syn_army_infl_data, syn_army_enlist_data;

create view army_enlist_obj(row_ix, col_ix, coef) as
select -3, ix, infl*cost
from army_enlist, syn_army_enlist_data, syn_army_infl_data
where army_enlist.year = syn_army_infl_data.year
and army_enlist.length = syn_army_enlist_data.length;

rem #########
rem ROW VIEWS
rem #########
create view army_demand(ix, year) as
select rownum, year
from syn_army_demand_data;

create view army_demand_lb(row_ix, col_ix, coef) as
select ix, -2, demand
from army_demand, syn_army_demand_data
where army_demand.year = syn_army_demand_data.year;

rem ##################
rem MATRIX BLOCK VIEWS
rem ##################
create view army_block11(row_ix, col_ix, coef) as

from army_demand, army_enlist
where army_enlist.year + army_enlist.length - 1 >= army_demand.year and
army_enlist.year <= army_demand.year;

There is only column strip and row strip for this model. There are three data tables
used to create an instance of the model. The first simply hold the required troop strength
in each year. The second holds the (uninflated) cost per year of hiring a soldier of each
potential enlistment length. The final table holds the estimated inflation factor for each
year in the planning horizon.
The Steel Model

This problem is the multi-period steel production model `steelT2.mod` described in [FGK93]. The problem is to determine how many tons of steel to produce, send to inventory, and sell to maximize profits over many periods, while meeting constraints on the availability of the rolling mill.

```sql
create table stl_production_def ( 
    product char(20),
    initinv char(20),
    rate number,
    pcost number,
    hcost number);

create table stl_markets_def ( 
    product char(20),
    period date,
    revenue number,
    limit number);

create table stl_periods_def ( 
    period date,
    avail number);
```

    stl_Balance.period = stl_Sell.period;

There are three columns strips, corresponding to the distinct decisions of how much
steel to make, send to inventory, and sell in each time period. There are three rowstrips.
One corresponds to the mill availability constraints for each time period and the remaining
two are necessary to balance the flow of products from time period to time period.

There are three tables holding data for an instance of the model. The production
table holds for each product the initial inventory, the rate at which it can be produced,
the production cost, and the holding cost. The markets table contains the revenue
received and maximum amount that can be sold in each for each product and period. The *periods* table tells how much rolling mill time is available in each period.

This example gives an idea of how to deal with ordered sets of variables within ARMOS since we must balance the flow of steel from period to period within the model. Here we make use of the special SQL date functions to select the minimum or maximum period.

One other interesting feature of this model is this use of overlaid matrix blocks. Their use is often necessary whenever there is more than one set of technological coefficients for a block. Balance constraints, having both a +1 and -1 entry in the block, fall into this category.
Appendix B

In this appendix, we give a brief description of the commands and functionality of the ARMOS system.

list: This command displays the names of models stored in SysModels table.

load <modelname>: Loading a model is the first thing a user needs to do to access a model stored in system tables. If the model specified is not in the ARMOS database, an error message appears indicating this.

matrix: Once a model is successfully loaded, the block schematic view can be displayed by typing matrix command. This commands prints the column strip, row strip and block names of the model, in a schematic format. Below is the block schematic view of the production distribution model described earlier.

```
RDDOMS > matrix

rowlower  produce  ship  assign  rowupper
prodrow   rlower1  block11 block12  0  rupper1
shiprow   rlower2  0      block22 block23 rupper2
centrow   rlower3  0      0      block33 rupper3
colupper  cupper1  +inf   +inf
collower  0      0      0
objective obj1   obj2   obj3
```

set <instancename>: The system’s instance management is performed by the set command. This command associates an instance name with the data tables used to create an instance of the problem. When this command is called, the system checks the SysInstances table to see whether there exists data table names specified for the instance name before. If the result is affirmative, those data table names are copied to the system table SysData. Otherwise, the user is asked to enter the data table names for
this new instance of the model. These names are recorded to SysInstances and then copied to SysData immediately. After a model is loaded, the set command can be called many times to create different instances.

show <blockname(s)>: Once an instance is set, it is possible to view instance matrix for a particular block of the model with show <blockname(s)> command. This capability may be quite useful for analyzing the instance. Arguments to show can be a single block name or a list of block names. A dash as an argument stands for all the model blocks.

solve: This command is the heart of our system. It actually performs all the interaction with the solver. When the solve command is called, the system generates the actual matrix (triplets) for the instance and loads it to the solver. After the solution is found, it creates the proper tables and puts back the solution values associated with the column strips and row strips into these solution tables. The solution table names for the particular instance solved are recorded in SysSols for future reference. Several statistical information such as run date, run time, elapsed time are recorded in SysRuns.

display <r/c> <tablename>: To display the solution values obtained by the solver, the display command is used. The syntax of the display command is display <r/c> <tablename>, where <tablename> is the name of the particular solution table you wish to view, and <r/c> is “r” if the solution to be viewed is a row strip and “c” if it is a column strip.

text <viewname(s)>: This command is for displaying the SQL commands used to create views for row and column strips and model blocks. This capability is particularly useful for report generation and debugging purposes at model generation phase. Argument to text can be a single view name or a list of view names. A dash as an argument stands
for all the views used in model.
