**INTRODUCTION TO LINEAR OPTIMIZATION
ISYE 6661**

Arkadi Nemirovski

Fall 2018

Preface

To make decisions optimally is one of the basic desires of a human being. In (relatively rare!) situations where one can quantify both candidate decisions (i.e., to represent them as points x varying in certain well-defined set X) and the criteria we are interested in (that is, to represent these criteria as real-valued function of $x \in X$), the problem of optimal decision making falls in the scope of Mathematics, specifically, the area called *Optimization*. A part of Optimization is *Mathematical Programming* interested in the optimization problems of the form

$$\max_x \{f_0(x) : x \in X\} \quad (*)$$

where the *feasible set* X is a subset of the space \mathbf{R}^n of real n -dimensional vectors x , and the *objective* f is a real-valued function. A typical description of the feasible set X of a Mathematical Programming (MP) problem is by a finite *system of constraints* $f_i(x) \leq g_i$:

$$X = \{x \in \mathbf{R}^n : f_i(x) \leq b_i, 1 \leq i \leq m\},$$

where $f_i(x)$ are given real-valued functions of n variables x , and b_i are given reals. Thus, a generic MP problem (or MP *program*) is of the form

$$\max_x \{f(x) : f_i(x) \leq b_i, i = 1, \dots, m\} \quad (!)$$

In other words, Mathematical Programming deals with the case when our candidate decisions can be encoded by vectors x of certain dimension n and we are interested in finitely many criteria represented by real-valued functions $f(x), f_1(x), \dots, f_m(x)$. Since in general it is impossible to optimize simultaneously more than one criteria (usually, you cannot simultaneously be as wealthy as possible and as healthy as possible), (!) treats the criteria “asymmetrically:” we impose bounds on all but one of the criteria and optimize the remaining criterion (optimize health, not allowing wealth to become too low, so to speak).

Linear Optimization (called also *Linear Programming*) is part of Optimization Theory handling *Linear Optimization problems*, those where the objective $f(x)$ and the constraints $f_i(x)$ are linear functions of x :

$$f(x) = c^T x = \sum_{j=1}^n c_j x_j, \quad f_i(x) = a_i^T x = \sum_{j=1}^n a_{ij} x_j.$$

LO is the simplest and the most frequently used in applications part of Mathematical Programming. Some of the reasons are:

- reasonable “expressive power” of LO — while the world we live in is mainly nonlinear, linear dependencies in many situations can be considered as quite satisfactory approximations of actual nonlinear dependencies. At the same time, a linear dependence is easy to specify, which makes it realistic to specify data of Linear Optimization models with many variables and constraints;
- existence of extremely elegant, rich and essentially complete mathematical theory of LO;
- last, but by far not least, existence of extremely powerful solution algorithms capable to solve to optimality in reasonable time LO problems with tens and hundreds of thousands of variables and constraints.

In our course, we will focus primarily on “LO machinery” (LO Theory and Algorithms), leaving beyond our scope practical applications of LO which are by far too numerous and diverse to be even outlined in a single course. The brief outline of the contents is as follows:

1. LO Modeling, including instructive examples of LO models and “calculus” of LO models – collection of tools allowing to recognize the possibility to pose an optimization problem as an LO program;
2. LO Theory – geometry of LO programs, existence and characterization of optimal solutions, theory of systems of linear inequalities and duality;
3. LO Algorithms, including Simplex-type and Interior Point ones, and the associated complexity issues.

I apologize in advance for possible typos and will be extremely grateful to those bringing the typos, or whatever other shortcomings of the Notes, to my attention.

Arkadi Nemirovski,
December 1, 2011.

Main Notational Conventions

Vectors and matrices. By default, all vectors in this course are column vectors. Usually, we utilize “MATLAB notation:” a vector with coordinates x_1, \dots, x_n is written down as $x = [x_1; \dots; x_n]$. More generally, if A_1, \dots, A_m are matrices with the same number of columns, we write $[A_1; \dots; A_m]$ to denote the matrix which is obtained when writing A_2 below A_1 , A_3 below A_2 , and so on. If A_1, \dots, A_m are matrices with the same number of rows, then $[A_1, \dots, A_m]$ stands for the matrix which is obtained when writing A_2 to the right of A_1 , A_3 to the right of A_2 , and so on. For example,

$$[1, 2, 3, 4] = [1; 2; 3; 4]^T, \quad [[1, 2; 3, 4], [5, 6; 7, 8]] = [1, 2, 5, 6; 3, 4, 7, 8] = \begin{bmatrix} 1 & 2 & 5 & 6 \\ 3 & 4 & 7 & 8 \end{bmatrix}.$$

$\text{Diag}\{A_1, A_2, \dots, A_m\}$ denotes the block-diagonal matrix with the diagonal blocks A_1, \dots, A_m . For example,

$$\text{Diag}\{[1, 2], 3, [4, 5; 6, 7]\} = \begin{bmatrix} 1 & 2 & & \\ & & 3 & \\ & & & 4 & 5 \\ & & & 6 & 7 \end{bmatrix}$$

where blank spaces are filled with zeros.

For a square nonsingular matrix A , A^{-T} means $[A^{-1}]^T$.

The zero vectors and matrices are, as always, denoted by 0 ; if we have reasons to point out the sizes of a zero vector/matrix, we write something like $0_{3 \times 4}$. The unit $m \times m$ matrix is denoted by I or I_m .

We write $A \succeq B$ (or, which is the same, $B \preceq A$) to express the fact that A, B are symmetric matrices of the same size such that $A - B$ is positive semidefinite; $A \succ B$ (or, which is the same, $B \prec A$) means that A, B are symmetric matrices of the same size such that $A - B$ is positive definite.

Lecture 1

Introduction to LO: Examples of LO Models

In this lecture, we define the main entity we are interested in our course – a *Linear Optimization problem*, provide a number of instructive examples and address the question of when an optimization problem can be posed as an LO one.

1.1 LO Program: Definition and Examples

1.1.1 Definitions and Terminology

An LO program

A *Linear Optimization problem*, or program (called also *Linear Programming* problem/program, abbreviations LO and LP) is the problem of optimizing a *linear function* $c^T x$ of an n -dimensional vector x under *finitely many linear* equality and nonstrict inequality constraints. For example, the following Mathematical Programming problems

$$\min_x \left\{ x_1 : \begin{cases} x_1 + x_2 \leq 20 \\ x_1 - x_2 = 5 \\ x_1, x_2 \geq 0 \end{cases} \right\} \quad (1.1.1)$$

and

$$\max_x \left\{ x_1 + x_2 : \begin{cases} 2x_1 \geq 20 - x_2 \\ x_1 - x_2 = 5 \\ x_1 \geq 0 \\ x_2 \leq 0 \end{cases} \right\} \quad (1.1.2)$$

are LO programs. In contrast to this, the optimization problems

$$\min_x \left\{ \exp\{x_1\} : \begin{cases} x_1 + x_2 \leq 20 \\ x_1 - x_2 = 5 \\ x_1, x_2 \geq 0 \end{cases} \right\} \quad (1.1.3)$$

and

$$\max_x \left\{ x_1 + x_2 : \begin{cases} ix_1 \geq 20 - x_2, i = 2, 3, \dots \\ x_1 - x_2 = 5 \\ x_1 \geq 0 \\ x_2 \leq 0 \end{cases} \right\} \quad (1.1.4)$$

are *not* LO programs: (1.1.3) has a nonlinear objective, and (1.1.4) has infinitely many constraints.

A careful reader could say that (1.1.2) is “the same” as (1.1.1) (since the exponent is monotone, it is the same what to minimize, x_1 or $\exp\{x_1\}$). Similarly, (1.1.4) is “the same” as (1.1.2), since for $x_1 \geq 0$, the infinitely many constraints $ix_1 + x_2 \geq 20$, $i = 2, 3, \dots$ are equivalent to the single constraint $2x_1 + x_2 \geq 20$. Note, however, that we classify optimization problems according to *how they are presented*, and not according to *what they can be equivalent/reduced to*.

Now, we can somehow “standardize” the format in which an LO program is presented. Specifically,

- every linear equality/inequality can be equivalently rewritten in the form where the left hand side is a weighted sum $\sum_{j=1}^n a_j x_j$ of variables x_j with coefficients, and the right hand side is a real constant; e.g., $2x_1 \geq 20 - x_2$ is equivalent to $2x_1 + x_2 \geq 20$;
- the sign of a nonstrict linear inequality always can be made “ \leq ”, since the inequality $\sum_j a_j x_j \geq b$ is equivalent to $\sum_j [-a_j] x_j \leq [-b]$;
- a linear equality constraint $\sum_j a_j x_j = b$ can be represented equivalently by the pair of opposite inequalities $\sum_j a_j x_j \leq b$, $\sum_j [-a_j] x_j \leq [-b]$;
- to minimize a linear function $\sum_j c_j x_j$ is exactly the same to maximize the linear function $\sum_j [-c_j] x_j$.

Canonical form of an LO program. In view of the above observations, every LO program can be equivalently written down as a problem of maximizing a linear objective under finitely many nonstrict linear inequality constraints of the “ \leq ”-type, i.e., in the *canonical* form

$$\begin{aligned}
 \text{Opt} &= \max_x \left\{ \sum_{j=1}^n c_j x_j : \sum_{j=1}^n a_{ij} x_j \leq b_i, 1 \leq i \leq m \right\} && \text{[“term-wise” notation]} \\
 \Leftrightarrow \text{Opt} &= \max_x \left\{ c^T x : a_i^T x \leq b_i, 1 \leq i \leq m \right\} && \text{[“constraint-wise” notation]} \\
 \Leftrightarrow \text{Opt} &= \max_x \left\{ c^T x : Ax \leq b \right\} && \text{[“matrix-vector” notation]}
 \end{aligned} \tag{1.1.5}$$

where $c = [c_1; \dots; c_n]$, $a_i = [a_{i1}; \dots; a_{in}]$, $A = [a_1^T; a_2^T; \dots; a_m^T]$, $b = [b_1; \dots; b_m]$.

Standard form of an LO program. An LO program in the *standard* form reads

$$\begin{aligned}
 \text{Opt} &= \max_x \left\{ \sum_{j=1}^n c_j x_j : \begin{array}{l} \sum_{j=1}^n a_{ij} x_j = b_i, 1 \leq i \leq m \\ x_j \geq 0, j = 1, \dots, n \end{array} \right\} && \text{[“term-wise” notation]} \\
 \Leftrightarrow \text{Opt} &= \max_x \left\{ c^T x : \begin{array}{l} a_i^T x = b_i, 1 \leq i \leq m \\ x_j \geq 0, 1 \leq j \leq n \end{array} \right\} && \text{[“constraint-wise” notation]} \\
 \Leftrightarrow \text{Opt} &= \max_x \left\{ c^T x : Ax = b, x \geq 0 \right\} && \text{[“matrix-vector” notation]}
 \end{aligned} \tag{1.1.6}$$

where $c = [c_1; \dots; c_n]$, $a_i = [a_{i1}; \dots; a_{in}]$, $A = [a_1^T; a_2^T; \dots; a_m^T]$, $b = [b_1; \dots; b_m]$. As compared with (1.1.5), in the standard form of an LO all “general” linear constraints are equalities, and the inequality constraints are *sign constraints*, specifically, the restrictions of nonnegativity, imposed on all variables. The standard form is as “universal” as the canonical one:

Observation 1.1.1 *Every LO program can be straightforwardly converted into an equivalent program in the standard form.*

Proof. We lose nothing by assuming that the original form of the program is the canonical one, specifically,

$$\max_y \{c^T y : Py \leq p\} \quad (!)$$

(note change in the notation). Now, to say that $Py \leq p$ is exactly the same as to say that $Py + u = p$ for certain *nonnegative* vector u ; in addition, every real vector y can be represented as the difference of two nonnegative vectors: $y = v - w$. It follows that (!) is equivalent to the problem

$$\max_{x=[u;v;w]} \{c^T x := d^T[v - w] : Ax := B(v - w) + u = b := p, x \geq 0\}$$

which is an LO in the standard form. \square

In the sequel, when investigating the “geometry” of LO, it will be more convenient to use the canonical form of an LO program; the standard form is preferable when presenting LO algorithms.

1.1.2 LO Terminology

We are about to present the most basic “vocabulary” of LO. For the sake of definiteness, in our presentation we refer to the canonical format of an LO program (1.1.5), leaving the “translation” to the case of a program in the standard form to the reader. The vocabulary is as follows:

- The variable vector x in (1.1.5) is called the *decision vector* of the program; its entries x_j are called *decision variables*. The linear function $c^T x$ is called the *objective function* (or just *objective*) of the problem, and the inequalities $a_i^T x \leq b_i$ are called the *constraints*. Sometimes, with slight abuse of wording, we refer to the vector c itself as to the objective;
- The *structure* of (1.1.5), given the way we are writing the problem down, reduces to the *sizes* m (number of constraints) and n (number of variables). The *data* of an LO program is the collection of numerical values of the coefficients in the *cost vector* (or simply *objective*) c , in the *right hand side vector* b and in the *constraint matrix* A ;
- A *solution* to (1.1.5) is an arbitrary value of the decision vector. A solution x is called *feasible* if it satisfies the constraints: $Ax \leq b$. The set of all feasible solutions is called the *feasible set* of the program; the program is called *feasible*, if the feasible set is nonempty, and is called *infeasible* otherwise;
- Given a program (1.1.5), there are three possibilities:
 - the program is infeasible. In this case, its optimal value Opt , by definition, is $-\infty$ (this convention is logical, since in the case in question one cannot point out a feasible solution with the value of the objective $> -\infty$);
 - the program is feasible, and the objective is *not* bounded from above on the feasible set, meaning that for every real a one can point out a feasible solution x such that $c^T x > a$. In this case, the program is called *unbounded*, and its optimal value Opt is, by definition, $+\infty$.

The program which is not unbounded is called *bounded*; a program is bounded iff its objective is bounded from above on the feasible set (e.g., due to the fact that the latter is empty);

- the program is feasible, and the objective is bounded from above on the feasible set: there exists a real a such that $c^T x \leq a$ for all feasible solutions x . In this case, the optimal value Opt is the supremum, over the feasible solutions, of the values of the objective at a solution.
- a solution to the program is called *optimal*, if it is feasible, and the value of the objective at the solution equals to Opt . A program is called *solvable*, if it admits an optimal solution.

Remarks. A. The above terminology is aimed at the *maximization* LO in the canonical form. The terminology in the case of a *minimization* problem “mirrors” the one we have described, specifically,

- the optimal value of an infeasible program is $+\infty$,
- the optimal value of a feasible and *unbounded* program (unboundedness now means that the objective to be minimized is not bounded *from below* on the feasible set) is $-\infty$, while the optimal value of a *bounded and feasible* LO is the *infimum* of values of the objective at feasible solutions to the program.

B. The notions of feasibility, boundedness, solvability and optimality can be straightforwardly extended from LO programs to arbitrary MP ones. With this extension, a solvable problem definitely is feasible and bounded (why?), while the inverse not necessarily is true, as is illustrated by the program

$$\text{Opt} = \max_x \{-\exp\{-x\} : x \geq 0\},$$

where the optimal value – the supremum of the values taken by the objective at the points of the feasible set – clearly is 0; this value, however, is not achieved – there is no feasible solution where the objective is equal to $0 = \text{Opt}$, and, as a result, the program is unsolvable. Thus, in general, the facts that an optimization program has a “legitimate” – real, and not $\pm\infty$ – optimal value, is *strictly weaker* than the fact that the program is solvable (i.e., has an optimal solution). In LO the situation is much better; eventually we shall prove that *an LO program is solvable iff it is feasible and bounded*.

1.1.3 Instructive Examples

Here we present a short series of standard examples of LO problems. In every one of them, we start with certain semi-verbal story and then “translate” this story into an LO program; this is called *modeling* – building a mathematical model, in our case, of the LO type, of a “practical” situation. It should be stressed that in applications of Optimization modeling plays the crucial role: on one hand, we need to end up with a model which is not “oversimplified,” that is, captures all important for the application in question relations and dependencies between the entities involved, and, on the other hand, is not too complicated, so that we can specify all the relevant data and process the resulting problem numerically at a reasonable computational cost. A proper balance between these two conflicting goals requires both deep understanding of the subject area to which the application belongs and good knowledge of optimization theory and algorithms. This being said, note that modeling per se, being a “go-between for reality and Mathematics,” is beyond the scope of our course.

Examples of LO models in OR

Diet problem. *There are n types of products and m types of nutrition elements. A unit of product # j contains p_{ij} grams of nutrition element # i and costs c_j . The daily consumption of a nutrition element # i should be at least a given quantity \underline{b}_i and at most a given quantity \bar{b}_i . Find the cheapest possible “diet” – mixture of products – which provides appropriate daily amounts of every one of the nutrition elements.”*

Denoting x_j the amount of j -th product in a diet, the LO model of the problem reads¹

$$\begin{array}{ll}
 \min_x & \sum_{j=1}^n c_j x_j \quad \text{[Diet's cost to be minimized]} \\
 \text{subject to} & \left. \begin{array}{l} \sum_{j=1}^n p_{ij} x_j \geq \underline{b}_i \\ \sum_{j=1}^n p_{ij} x_j \leq \bar{b}_i \end{array} \right\}, 1 \leq i \leq m \quad \left[\begin{array}{l} \text{upper and lower bounds on the contents} \\ \text{of nutrition elements in a diet} \end{array} \right] \\
 & x_j \geq 0, 1 \leq j \leq n \quad \left[\begin{array}{l} \text{you cannot put into a diet a} \\ \text{negative amount of a product} \end{array} \right]
 \end{array} \tag{1.1.7}$$

The Diet problem is one of the first LO models, and today it is routinely used in many areas, e.g., in mass-production of poultry. As about nourishment of human beings, the model is of no much use, since it completely ignores factors like food's taste, food diversity requirements, etc.

Here is the optimal daily human diet as computed by the software at <http://www-neos.mcs.anl.gov/CaseStudies/dietpy/WebForms/index.html> (when solving the problem, I allowed to use all 64 kinds of food offered by the code):

Food	Serving	Cost
Raw Carrots	0.12 cups shredded	0.02
Peanut Butter	7.20 Tbsp	0.25
Popcorn, Air-Popped	4.82 Oz	0.19
Potatoes, Baked	1.77 cups	0.21
Skim Milk	2.17 C	0.28

Daily cost \$ 0.96

Production planning. *A factory consumes R types of resources (electricity, raw materials of various kinds, various sorts of manpower, processing times at different devices, etc.) and produces P types of products. There are n possible production processes, j -th of them can be used with “intensity” x_j (you may think of these intensities as of fractions of the planning period (say, 1 month) during which a particular production process is used). Used at unit intensity, production process # j consumes A_{rj} units of resource r , $1 \leq r \leq R$, and yields C_{pj} units of product p , $1 \leq p \leq P$. The profit of selling a unit of product p is c_p . Given upper bounds b_1, \dots, b_R on the amounts of various resources available during the planning period, and lower bounds d_1, \dots, d_P on the amount of products to be produced, find a production plan which maximizes the profit under the resource and the demand restrictions.*

¹Here and in the subsequent examples, we do not bother to convert the model into a specific form, e.g., the canonical one, since this (completely straightforward and “mechanical”) process would only obscure the construction of a model. Note that existing LO solvers also do not require from a user to input the problem in certain particular form and use preprocessors to convert an LO program into the format directly accessible for the solver. A “standard” format is convenient when investigating LO's as “mathematical beasts,” not when building LO models!

Denoting by x_j the intensity at which production process j is used, the LO model reads:

$$\begin{aligned}
 & \max_x \quad \sum_{j=1}^n \left(\sum_{p=1}^P c_p C_{pj} \right) x_j && \text{[profit to be maximized]} \\
 & \text{subject to} && \\
 & \quad \sum_{j=1}^n A_{rj} x_j \leq b_r, \quad 1 \leq r \leq R && \text{[upper bounds on consumed resources should be met]} \\
 & \quad \sum_{j=1}^n C_{pj} x_j \geq d_p, \quad 1 \leq p \leq P && \text{[lower bounds on products' yield should be met]} \\
 & \quad \left. \begin{array}{l} \sum_{j=1}^n x_j \leq 1 \\ x_j \geq 0, \quad 1 \leq j \leq n \end{array} \right\} && \left[\begin{array}{l} \text{total intensity should be } \leq 1 \text{ and} \\ \text{intensities must be nonnegative} \end{array} \right]
 \end{aligned} \tag{1.1.8}$$

Note that the simple model we have presented tacitly assumes that all what is produced can be sold, that there are no setup costs when switching from one production process to another one, that products are infinitely divisible (we produce needles rather than Boeings, so to speak), and makes a lot of other implicit assumptions.

Inventory. An inventory operates over the time horizon $1, \dots, T$ (say, T days) and handles K types of products.

- Products share common warehouse with storage space C . The space required to store a unit of product k in the warehouse is $c_k \geq 0$, and the holding cost (the per-day cost of storing a unit of product k in the warehouse) is h_k .
- The inventory is replenished via ordering from a supplier; a replenishment order sent in the beginning of day t is executed immediately, and ordering a unit of product k costs o_k .
- The inventory is affected by external demand which amounts to d_{tk} units of product k in day t . While backlogged demand is allowed, a day-long delay in supplying a customer by unit of product k costs p_k .

Given the initial amounts s_{0k} , $k = 1, \dots, K$, of products in warehouse, all the cost coefficients (which are nonnegative) and the demands d_{tk} ,² We want to specify the replenishment orders v_{tk} (v_{tk} is the amount of product k which is ordered from the supplier at the beginning of period t) in such a way that at the end of period T there is no backlogged demand, and we want to meet this requirement at as small total inventory management costs as possible.

In order to convert this story into an LO model, we first introduce the *state variables* s_{tk} representing the amount of product k in the warehouse at the end of period t (or, which is the same, at the beginning of period $t + 1$); we allow these state variables to be negative as well as positive, with a negative value of s_{tk} interpreted as “at the end of period t , the inventory owes the customers $|s_{tk}|$ units of product k ”. With this convention, our problem can be modeled as

²The latter assumption — that the demands are known in advance — more often than not is unrealistic. This issue will be addressed in the mean time, when speaking about LO problems with uncertain data.

the optimization program

$$\begin{aligned}
& \min_{U,v,s} && U \\
& \text{subject to} && \\
& U = \sum_{k=1}^K \sum_{t=1}^T [o_k v_{tk} + h_k \max[s_{tk}, 0] + p_k \max[-s_{tk}, 0]] & (a) \\
& s_{tk} = s_{t-1,k} + v_{tk} - d_{tk}, 1 \leq t \leq T, 1 \leq k \leq K & (b) \\
& \sum_{k=1}^K c_k \max[s_{tk}, 0] \leq C, 1 \leq t \leq T & (c) \\
& s_{Tk} \geq 0, 1 \leq k \leq K & (d) \\
& v_{tk} \geq 0, 1 \leq k \leq K, 1 \leq t \leq T & (e)
\end{aligned} \tag{1.1.9}$$

(the s -variables s_{tk} have $t \geq 1$, s_{0k} being part of problem's data). In this model,

- the variable U is the overall inventory management cost which we want to minimize;
- constraint (a) expresses the fact that U indeed is the overall inventory management cost – the total, over the K products and the T days, ordering cost ($o_k v_{tk}$), holding cost ($h_k \max[s_{tk}, 0]$), and penalty for backlogged demand ($p_k \max[-s_{tk}, 0]$) associated with product k and period t . Further, constraints (b) express the evolution of states, and constraints (c) express the restrictions on the space available for storing the products.

The implicit assumptions underlying the latter claims are as follows: the replenishment orders v_{tk} are issued in the beginning of day t and are executed immediately. As a result, the amount of product k in the inventory in the beginning of day t jumps from $s_{t-1,k}$ to $s_{t-1,k} + v_{tk}$. Immediately after this, the demands d_{tk} of day t become known and the products are shipped to the customers, which reduces – again immediately! – the inventory level by d_{tk} , so that the resulting level $s_{t-1,k} + v_{tk} - d_{tk}$, if nonnegative, is the amount of product k stored in the inventory during day t , otherwise the modulus of this level is the backlogged demand on product k during day t .

From the story we have just told we see, first, that the states s_{tk} of the inventory, as defined above, evolve according to (b). Second, our expenses, associated with product k , in day t include the ordering cost $o_k v_{tk}$, and on the top of it, *either* the holding cost $h_k s_{tk}$ (this is so if s_{tk} is nonnegative), *or* the penalty $p_k [-s_{tk}]$ for backlogged demand (when s_{tk} is negative). We see that (a) correctly represents the expenses. Further, we see that the “physical” amount of product k stored in the warehouse during day t is $\max[s_{tk}, 0]$, so that (c) correctly represents the restriction on the space available for storage of products.

- constraint (d) expresses equivalently the requirement that at the end of the planning period (i.e., at the end of day T) there is no backlogged demand.
- finally, constraints (e) express the implicit assumption that we can only order from the supplier, while return of products to the supplier is forbidden.

Note that we lose nothing when replacing the *equality* constraint (1.1.9.a) with the *inequality* constraint

$$U \geq \sum_{k=1}^K \sum_{t=1}^T [o_k v_{tk} + h_k \max[s_{tk}, 0] + p_k \max[-s_{tk}, 0]] \tag{a'}$$

which corresponds to minimizing an *upper bound* U on the actual inventory management cost; since nothing prevents us from setting this bound to be equal to the right hand side in (1.1.9.a) (which in any case will be enforced by minimization), the modified in this way problem is equivalent to the original one. In the remaining discussion, we assume that (1.1.9.a) is replaced with (a').

We have modeled our verbal problem by (a slightly modified version of) (1.1.9); note, however, that the resulting model is *not* an LO program, due to the presence of *nonlinear* in our design variables terms $\max[\pm s_{tk}, 0]$. We are about to demonstrate (pay maximal attention to this construction!) that we *can handle this type of nonlinearities via LO*. Specifically, assume that we have a constraint of the form

$$\alpha_1 \text{Term}_1(y) + \dots + \alpha_M \text{Term}_M(y) \leq b, \quad (!)$$

where α_ℓ are *nonnegative* constant coefficients, b is a constant, and every term $\text{Term}_\ell(y)$ is either a linear function of our design variables y (let it be so for $L < \ell \leq M$), or is a *piecewise linear* function of the form

$$\text{Term}_\ell(y) = \max[a_{1\ell}^T y + b_{1\ell}, a_{2\ell}^T y + b_{2\ell}, \dots, a_{p\ell}^T y + b_{p\ell}] \quad (*)$$

(the latter is the case for $1 \leq \ell \leq L$).

Note that *converted equivalently to the form of (!), all constraints (a'), (1.1.9.b-e) are of this form*, which is an immediate corollary of the nonnegativity of the cost coefficients h_k , p_k and the space coefficients c_k .

Now, let us replace every piecewise linear term Term_ℓ in (!) with a new decision variable w_ℓ (“slack variable” in the slang of LO) and augment this action by imposing the constraints

$$w_\ell \geq a_{\nu\ell}^T y + b_{\nu\ell}, \quad 1 \leq \nu \leq p$$

on the original and the slack variables. As a result, the constraint (!) will be replaced by the system

$$\begin{aligned} \sum_{\ell=1}^L \alpha_\ell w_\ell + \sum_{\ell=L+1}^M \alpha_\ell \text{Term}_\ell(y) &\leq b \\ w_\ell &\geq a_{\nu\ell}^T y + b_{\nu\ell}, \quad 1 \leq \nu \leq p, 1 \leq \ell \leq L \end{aligned}$$

of *linear* in the variables y, w_1, \dots, w_L . Taking into account that $\alpha_1, \dots, \alpha_L$ are nonnegative, it is clear that *this system says about our original variables y exactly the same as the constraint (!)*, meaning that y can be extended, by properly chosen values of slack variables w_ℓ , $1 \leq \ell \leq L$, to a feasible solution of the system iff y satisfies (!). If now (!) is a constraint in certain optimization problem, then, augmenting the variables of the problem by slack variables w_ℓ and replacing the constraint in question with the above system, we arrive at an *equivalent* problem where the nonlinear constraint in question is replaced with a system of linear constraints. If all constraints with nonlinearities in an optimization problem admit the outlined treatment, we can apply the outlined procedure “constraint by constraint” and end up with an LO which is equivalent to the original problem.

Let us apply this recipe to problem (1.1.9) (with constraint (a) replaced with (a'), which, as we remember, keeps the problem intact up to equivalence). Specifically, we introduce the slack variables (upper bounds) y_{tk} for the quantities $\max[s_{tk}, 0]$ and z_{tk} for the quantities $\max[-s_{tk}, 0]$ and replace the nonlinearities with these upper bounds, augmenting the resulting system of constraints with linear constraints (constraints (f), (g) below) expressing equivalently the fact

that y_{tk} , z_{tk} indeed are upper bounds on the corresponding nonlinearities. The resulting program reads

$$\begin{aligned}
 & \min_{U, v, s, y, z} \quad U \\
 & \text{subject to} \\
 & U \geq \sum_{k=1}^K \sum_{t=1}^T [o_k v_{tk} + h_k y_{tk} + p_k z_{tk}] \quad (a) \\
 & s_{tk} = s_{t-1, k} + v_{tk} - d_{tk}, 1 \leq t \leq T, 1 \leq k \leq K \quad (b) \\
 & \sum_{k=1}^K c_k y_{tk} \leq C, 1 \leq t \leq T \quad (c) \\
 & s_{Tk} \geq 0, 1 \leq k \leq K \quad (d) \\
 & v_{tk} \geq 0, 1 \leq k \leq K, 1 \leq t \leq T \quad (e) \\
 & y_{tk} \geq s_{tk}, y_{tk} \geq 0, 1 \leq k \leq K, 1 \leq t \leq T \quad (f) \\
 & z_{tk} \geq -s_{tk}, z_{tk} \geq 0, 1 \leq k \leq K, 1 \leq t \leq T \quad (g)
 \end{aligned} \tag{1.1.10}$$

and is an LO program which is equivalent to (1.1.9) and thus models our inventory problem.

Warning: The outlined “eliminating nonlinearities” heavily exploits the facts that

- (1) (!) is a constraint with piecewise linear nonlinearities which are *maxima* of linear forms,
- (2) all the nonlinearities are to the left of “ \leq ”-sign, and
- (3) the coefficients at these nonlinearities are nonnegative.

Indeed, assume that we are given a constraint with the terms which are either linear functions of the variables, or piecewise linear functions “maximum of linear terms” multiplied by constant coefficients. We always can rewrite this constraint in the form of (!), but the coefficients at nonlinearities in this constraint not necessarily should be nonnegative. Of course, we can “move the coefficients into the nonlinearities”, noting that

$$c \max[a_1^T y + b_1, \dots, a_p^T y + b_p]$$

is either $\max[ca_1^T y + cb_1, \dots, ca_p^T y + cb_p]$ when $c \geq 0$, or $\min[ca_1^T y + cb_1, \dots, ca_p^T y + cb_p]$ when $c < 0$. Now all nonlinearities have coefficients 1 and are to the left of “ \leq ”, but there, in general, are two types of them: maxima of linear forms and minima of linear forms. The above construction shows that if *all the nonlinearities are maxima of linear forms*, we can eliminate them at the cost of introducing slack variables and converting (!) into a system of linear inequalities. The number of slack variables we need is equal to the number of nonlinearities we are eliminating, and the number of linear inequalities we end up with is by one greater than the total number of linear forms participating in the nonlinearities.” The situation changes dramatically when among the nonlinearities are minima of linear forms. Given such a nonlinearity, say, $\min[a_1^T y + b_1, \dots, a_p^T y + b_p]$, we can, of course, replace it with a slack variable w at the cost of augmenting the list of constraints by the constraint $w \geq \min[a_1^T x + b_1, \dots, a_p^T x + b_p]$ (“isolating” the nonlinearity, so to speak). The difficulty is that now this additional constraint cannot be immediately reduced to a system of linear inequalities: instead of expressing the fact that w is \geq the maximum of $a_i^T x + b_i$ over i , that is, that $w \geq a_1^T x + b_1$ AND $w \geq a_2^T x + b_2$ AND ... AND $w \geq a_p^T x + b_p$ (which is just a system of p linear inequalities on w and y), we need to express the fact that w is \geq the minimum of $a_i^T x + b_i$ over i , that is, that $w \geq a_1^T x + b_1$ OR $w \geq a_2^T x + b_2$ OR ... OR $w \geq a_p^T x + b_p$, which is *not* a system of linear inequalities on w, y . Of course, it is possible to eliminate nonlinearities of the min-type by “branching” on them: to eliminate nonlinearity $w \geq \min[a_1^T x + b_1, \dots, a_p^T x + b_p]$, we build p uncoupled problems where this nonlinearity is substituted subsequently by every one of the linear inequalities $w \geq a_i^T x + b_i$, $i = 1, \dots, p$. However, if we have several “bad” — requiring branching — nonlinearities in an optimization problem, when eliminating all of them, we need to consider separately all combinations of the

above substitutions across the bad nonlinearities. As a result, if in the original problem we have K “bad” piecewise linear nonlinearities and k -th of them involves p_k linear functions, their elimination results in the necessity to consider separately $N = p_1 p_2 \dots p_K$ “LO variants” of the original problem. Since the number of variants grows exponentially fast with the number of bad nonlinearities, this approach, at least in its outlined straightforward form, can be used only when K and p_i , $1 \leq i \leq K$, are small.

Transportation and Network Flows. Let us start with the story as follows.

There are I warehouses, i -th of them storing s_i units of product, and J customers, j -th of them demanding d_j units of product. Shipping a unit of product from warehouse i to customer j costs c_{ij} . Given the supplies s_i , the demands d_j and the costs C_{ij} , we want to decide on the amounts of product to be shipped from every warehouse to every customer. Our restrictions are that we cannot take from a warehouse more product than it has, and that all the demands should be satisfied; under these restrictions, we want to minimize the total transportation cost.

Introducing decision variables x_{ij} , with x_{ij} being the amount of product to be shipped from warehouse i to customer j , the story can be modeled by the LO program

$$\begin{aligned}
 \min_x \quad & \sum_{i,j} c_{ij} x_{ij} && \text{[transportation cost to be minimized]} \\
 \text{subject to} \quad & \sum_{j=1}^J x_{ij} \leq s_i, \ 1 \leq i \leq I && \text{[we should respect the capacities of the warehouses]} \\
 & \sum_{i=1}^I x_{ij} = d_j, \ j = 1, \dots, J && \text{[we should satisfy the demands]} \\
 & x_{ij} \geq 0, \ 1 \leq i \leq I, \ 1 \leq j \leq J && \text{[you cannot ship a negative amount of product]}
 \end{aligned} \tag{1.1.11}$$

We end up with what is called a *transportation problem*. Note that when building the model we have assumed implicitly that the product is infinitely divisible.

A far-reaching generalization of the transportation problem is the *multicommodity network flow problem* as follows. We are given a *network* (an oriented graph) — a finite set of *nodes* $1, \dots, n$ along with a finite set Γ of *arcs* — ordered pairs $\gamma = (i, j)$ of distinct ($i \neq j$) nodes. We say that an arc $\gamma = (i, j)$ *starts* at node i , *ends* at node j and *links* node i to node j . As an example, you may think of a road network, where the nodes are road junctions, and the arcs are the one-way segments of roads “from a junction to a neighboring one;” a 2-way road segment can be modeled by two opposite arcs. (Of course, many other interpretations of a network are possible). Now imagine that there are N types of “commodities” moving along the network, and let s_{ki} be the “external supply” of k -th commodity at node i . This supply can be positive (meaning that the node “pumps” into the network s_{ki} units of commodity k), negative (the node “drains” from the network $|s_{ki}|$ units of commodity k) and zero. You may think of k -th commodity as about the stream of cars originating within a time unit (say, one hour) at a particular node (say, at GaTech campus) and moving to a particular destination (say, Northside Hospital); the corresponding s_{ki} are zeros for all nodes i except for the origin and the destination ones. For the origin node i , s_{ki} is the per hour amount c of cars leaving the node for the destination in question, while for the destination node i , $s_{ki} = -c$, so that $|s_{ki}|$ is the per hour amount of cars of given origin arriving at the destination.³ Now, the propagation of commodity k through the network can be represented by a vector f^k with entries f_γ^k indexed by the arcs of the network;

³In our static “traffic illustration” we assume implicitly that the traffic is in steady state.

f_γ^k is the amount of the commodity moving through the arc γ . Such a vector is called a *feasible flow*, if it is nonnegative and meets the *conservation law* as follows: for every node i in the network, the total amount of the commodity k arriving at the node plus the supply s_{ki} of the commodity k at the node equals to the total amount of the commodity k leaving the node:

$$\sum_{p \in P(i)} f_{pi}^k + s_{ki} = \sum_{q \in Q(i)} f_{iq}^k,$$

where $P(i)$ is the set of all nodes p such that (p, i) is an arc in the network, and $Q(i)$ is the set of all nodes q such that (i, q) is an arc in the network.

The *multicommodity flow* problem reads: Given

- a network with n nodes $1, \dots, n$ and a set Γ of arcs,
- a number K of commodities along with supplies s_{ki} of nodes $i = 1, \dots, n$ to the flow of commodity k , $k = 1, \dots, K$,
- the per unit cost $c_{k\gamma}$ of transporting commodity k through arc γ ,
- the capacities h_γ of the arcs,

find the flows f^1, \dots, f^K of the commodities which are nonnegative, respect the conservation law and the capacity restrictions (that is, the total, over the commodities, flow through an arc does not exceed the capacity of the arc) and minimize, under these restrictions, the total, over the arcs and the commodities, transportation cost.

In our “traffic illustration,” you may think about a shipping cost $c_{k\gamma}$ as about the time required for a car to travel through arc γ (with this interpretation, $c_{k\gamma}$ should be independent of k), in which case the optimization problems becomes the problem of finding *social optimum* — the routing of cars in which the *total*, over all cars, traveling time of a car is as small as possible.

To write down an LO model of the problem, let us define the *incidence matrix* $P = [P_{i\gamma}]$ of a network as the matrix with rows indexed by the nodes $i = 1, \dots, n$ of the network and the columns are indexed by the arcs $\gamma \in \Gamma$ of the network, with the entry $P_{i\gamma}$

- equal to 1 when the arc γ starts at node i ,
- equal to -1 when the arc γ ends at node i ,
- equal to 0 in all remaining cases.

With this notation, the conservation law for a flow f , the supplies being s_1, \dots, s_n , reads (check it!)

$$\sum_{\gamma} P_{i\gamma} f_\gamma = s := [s_1; \dots; s_n].$$

Now we can write down an LO program modeling the multicommodity flow problem:

$$\begin{aligned} \min_{f^1, \dots, f^K} \quad & \sum_{k=1}^K \sum_{\gamma \in \Gamma} c_{i\gamma} f_\gamma^k \quad [\text{total transportation cost}] \\ \text{subject to} \quad & P f^k = s^k := [s_{k1}; \dots; s_{kn}], \quad k = 1, \dots, K \quad \left[\begin{array}{l} \text{flow conservation law for the} \\ \text{flow of every commodity} \end{array} \right] \\ & f_\gamma^k \geq 0, \quad 1 \leq k \leq K, \gamma \in \Gamma \quad [\text{flows must be nonnegative}] \\ & \sum_{k=1}^K f_\gamma^k \leq h_\gamma, \gamma \in \Gamma \quad [\text{we should respect bounds on capacities of the arcs}] \end{aligned} \tag{1.1.12}$$

Note that the transportation problem is a very specific case of the multicommodity flow problem. Indeed, in the situation of the transportation problem, let us start with $I + J$ -nodal graph with I red nodes representing warehouses and J green nodes representing the customers, and IJ arcs leading from every warehouse to every customer; the arc from i -th warehouse to j -th customer

has infinite capacity and transportation cost c_{ij} . Further, let us add to this graph one extra node, called *source*, and I arcs linking the source and the warehouses. The arc “source-warehouse # i ” is assigned with zero transportation cost and capacity s_i (the amount of product in warehouse i). Finally, let there be a single commodity, with external supply equal to $D = \sum_{j=1}^J d_j$ at the source node and equal to $-d_j$ at the green node # j (the node representing j -th customer). Clearly, the resulting single-commodity version of the multicommodity flow problem (1.1.12) is nothing but the transportation problem (1.1.11).

LO programs on networks form a special, extremely nice part of LO. Here is one of the most beautiful problems of this type — the *Maximal Flow* problem as follows: *We are given a network with arcs γ assigned with nonnegative capacities h_γ . One of the nodes is designated as source, another one – as sink. We are looking at the maximal flow from source to sink, that is, for the largest s such that the external supply “ s at the source, $-s$ at the sink, zero at all other nodes” corresponds to certain feasible flow respecting the arc capacity bounds.*

The LO model of this problem reads:

$$\begin{aligned} \max_{f,s} \quad & s \quad [\text{total flow from source to sink to be maximized}] \\ \text{subject to} \quad & \sum_{\gamma} P_{i\gamma} f_{\gamma} = \begin{cases} s, & i \text{ is the source node} \\ -s, & i \text{ is the sink node} \\ 0, & \text{for all other nodes} \end{cases} \quad [\text{flow conservation law}] \quad (1.1.13) \\ & f_{\gamma} \geq 0, \gamma \in \Gamma \quad [\text{flows in the arcs should be nonnegative}] \\ & f_{\gamma} \leq h_{\gamma}, \gamma \in \Gamma \quad [\text{we should respect arc capacities}] \end{aligned}$$

The beauty of Network Flow problems stems from the fact that one can utilize additional and very specific structure coming from the associated network; as a result, numerous Network Flow LO’s admit specialized highly efficient solution algorithms which *within their scope* by far outperform “general purpose” LO methods.

Engineering examples

Traditionally, LO models and algorithms were considered as part of Operations Research and as such were primarily associated with decision-making applications. Power of LO in engineering applications was realized essentially later, and “penetrating” of LO in these areas seems to be still in progress. Applications of this type include synthesis of linear controllers for discrete time linear dynamical systems, and various applications in Data Mining and Signal Processing. We present just two illustrations, one of them teaching us important “modeling tricks”, and the other one selected due to its crucial role in sparsity-oriented Signal Processing.

Fitting parameters in linear regression models. Imagine that we have observed m pairs “input $x^i \in \mathbf{R}^n$ to a “black box” — output $y^i \in \mathbf{R}$ of the black box.” Sometimes we have reasons to believe that this output is a corrupted by noise version of the “existing in the nature, but unobservable, ideal output” $y_*^i = [\theta^*]^T x^i$ which is just linear function of the inputs (this is called “linear regression model”). Our goal is to convert actual observations $x^i, y^i, 1 \leq i \leq m$, into estimates of the *unknown* vector of parameters θ^* . This problem would be easy, if there were no observation errors (y^i were exactly equal to $[\theta^*]^T x^i$) and we were possessing a reach enough set of observations, so that among the vectors x^1, \dots, x^m (“regressors” in the terminology of linear regression) there were $n = \dim \theta^*$ linearly independent. In this case the “true” vector of unknown parameters would be a solution to the system of linear equations $y^i = \theta^T x^i, 1 \leq i \leq m$,

in variables θ , the solution to this system being unique (since among the vectors x^1, \dots, x^m there are n linearly independent); it remains to note that to find the unique solution to a solvable system of linear equations is a simple Linear Algebra problem.

The situation changes dramatically when there are observation noises and/or the number n of “degrees of freedom” of the regression model – the dimension of the vector of parameters, or, which is the same, of the regressor vectors x^i – is larger than the number m of observations. Because of observation noises, the system

$$\theta^T x^i = y_i, \quad i = 1, \dots, m \quad (*)$$

in variables θ can become infeasible (this will be typically the case when $m > n$) and even when feasible, it is unclear what is the relation of its solution(s) to the true value of the parameter vector (which now is *not* a solution to the system). Likewise, with a non-unique solution (this will be typically the case when $m < n$), it is unclear which one of the solutions to the system to take — and this is so even if there are no observation errors, that is, when we know in advance that the true vector of parameters is among the solutions to the system.

There exists a wide (and constantly extending) spectrum of various techniques for parameter estimation in a linear regression, differing from each other primarily in what is our a priori information on the nature of the observation errors, the structure of the true vector of parameters, etc.; some of these techniques heavily utilize LO. For example, we can choose a simple “discrepancy measure” – a kind of distance between the vector of outputs $X\theta = [[x^1]^T\theta; \dots; [x^m]^T\theta]$ of our hypothetical model (here X is the $m \times n$ matrix with the rows $[x^1]^T, \dots, [x^m]^T$) and the vector of observed outputs $y = [y^1; \dots; y^m]$, and look for the vector of parameters which minimizes this discrepancy. This amounts to the necessity to solve the optimization problem

$$\min_{\theta} \phi(X\theta, y), \quad (*)$$

where $\phi(u, v)$ is the discrepancy between vectors u and v . Note that this approach does not make much sense when the number of observations m is less than the number n of unknown parameters (think why); it is used, if at all, when $m \gg n$.

There are two simple cases when the outlined problem reduces to LO. The first is the case when we are interested in the *uniform fit*:

$$\phi(u, v) = \|u - v\|_{\infty} := \max_{1 \leq i \leq \dim u} |u_i - v_i|.$$

The second case corresponds to the ℓ_1 fit

$$\phi(u, v) = \|u - v\|_1 := \sum_{i=1}^{\dim u} |u_i - v_i|.$$

- With the uniform fit, (*) reads

$$\min_{\theta} \max_{1 \leq i \leq m} |[x^i]^T \theta - y_i|;$$

while literally this is not an LO program, we can easily convert it to the LO form by introducing slack variable τ which should be an upper bound on all the quantities $|[x^i]^T \theta - y_i|$ and minimizing this bound. The resulting problem reads

$$\min_{\tau, \theta} \{ \tau : [x^i]^T \theta - y_i \leq \tau, y_i - [x^i]^T \theta \leq \tau, 1 \leq i \leq m \},$$

which is an LO program.

- with the ℓ_1 -fit, (*) reads

$$\min_{\theta} \sum_{i=1}^m |[x^i]^T \theta - y_i|, \quad (1.1.14)$$

which again is *not* an LO program. There are two ways to convert it into LO – a good and a bad one. The good way is to note that $|a| = \max[a, -a]$, that is, $|[x^i]^T \theta - y_i|$ is the maximum of two linear forms of θ , and to use the trick we remember from processing the inventory problem; the resulting LO equivalent to the problem of interest reads

$$\min_{\theta, w} \left\{ \sum_{i=1}^m w_i : [x^i]^T \theta - y_i \leq w_i, y_i - [x^i]^T \theta \leq w_i, 1 \leq i \leq m \right\}.$$

A bad way is to note that $\sum_{i=1}^m |a_i| = \max_{\epsilon_1 = \pm 1, \epsilon_2 = \pm 1, \dots, \epsilon_m = \pm 1} \sum_{i=1}^m \epsilon_i a_i$, which allows to write the problem of interest down as an LO solely in the original variables θ , augmented by a *single* slack variable τ , specifically, as

$$\min_{\tau, \theta} \left\{ \tau : \tau \geq \sum_{i=1}^m \epsilon_i [[x^i]^T \theta - y_i] \quad \forall \epsilon_1 = \pm 1, \epsilon_2 = \pm 1, \dots, \epsilon_m = \pm 1 \right\}. \quad (1.1.15)$$

While being legitimate, this conversion indeed is bad, since we end up with an LO with 2^m linear constraints; handling the resulting LO program will be completely impractical already for $m = 10$, and will be impossible for $m = 30$.

Sparsity-oriented Signal Processing and ℓ_1 minimization, I: Compressed Sensing.

Let us start with *Compressed Sensing* which addresses, essentially, the same linear regression problem as above, but in the case opposite to the one we have just considered, specifically, when the number of observations m is much less than the number n of unknown parameters. Thus, we are in the situation when the m -dimensional vector of observations is obtained from an *unknown* n -dimensional vector of parameters θ^* according to

$$y = X\theta^*, \quad (!)$$

(for the time being, there is no observation error), and X is a given $m \times n$ *sensing matrix*. Our goal is to recover θ^* given y , and the Compressed Sensing situation is the one where $m \ll n$. At a first glance, our goal is unreachable: when $m \ll n$, (!), treated as a system of linear equations in variables θ , is heavily underdetermined: if solvable, it has infinitely many solutions, including those which are very far from each other, since the solution set of (!), if nonempty, is unbounded (why?). It follows that we have no chances to recover the true solution, unless we augment the observations with certain additional information. In Compressed Sensing, this additional information is the one of *sparsity* of θ^* , specifically, the a priori knowledge of an upper bound $s \ll m$ on the number of nonzero entries in θ^* .

Note that in many applications we indeed can be sure that the true vector of parameters θ^* is sparse. Consider, e.g., the following story about signal detection (from the applied viewpoint, this story is *not* of “linear regression” flavor, but the mathematical model looks exactly the same). *There are n locations where signal transmitters*

could be placed, and m locations with the receivers. The contribution of a signal of unit magnitude originating in location j to the signal measured by receiver i is a known quantity X_{ij} , and signals originating in different locations merely sum up in the receivers; thus, if θ^* is the n -dimensional vector with entries θ_j^* representing the magnitudes of signals transmitted in locations $j = 1, 2, \dots, n$, then the m -dimensional vector y of measurements of the m receivers is $y = X\theta^*$. Given this vector, we intend to recover θ^* .

Now, if the receivers are hydrophones registering noises emitted by submarines in certain part of Atlantic, tentative positions of submarines being discretized with resolution 500 m, the dimension of the vector θ^* (the number of points in the discretization grid) will be in the range of tens of thousands, if not tens of millions. At the same time, the total number of submarines (i.e., nonzero entries in θ^*) can be safely upper-bounded by 50, if not by 20.

In view of the just outlined interpretation of the situation we are in, in the sequel we use the words “true signal” as an equivalent to the words “the true vector of parameters.”

Given in advance that θ^* has at most $s \ll m$ nonzero entries, the possibility of exact recovery of θ^* from observations y becomes quite natural. Indeed, let us try to recover θ by the following “brute force” search: we inspect, one by one, all subsets I of the index set $\{1, \dots, n\}$ — first the empty set, then n singletons $\{1\}, \dots, \{n\}$, then $\frac{n(n-1)}{2}$ 2-element subsets, etc., and each time try to solve the system of linear equations

$$y = X\theta, \quad \theta_j = 0 \text{ when } j \notin I;$$

when arriving for the first time at a solvable system, we terminate and claim that its solution is the true vector θ^* . It is clear that we will terminate before all sets I of cardinality $\leq s$ are inspected. It is also easy to show (do it!) that if every $2s$ distinct columns in X are linearly independent (when $m \geq 2s$, this indeed is the case for a matrix X in a “general position”⁴), then the procedure is correct — it indeed recovers the true vector θ^* .

A bad news is that the outlined procedure becomes completely impractical already for “small” values of s and n because of the astronomically large number of linear systems we need to process⁵. A partial remedy is as follows. The outlined approach is, essentially, a particular way to solve the optimization problem

$$\min\{\text{nnz}(\theta) : A\theta = y\}, \quad (*)$$

⁴Here and in the sequel, the words “in general position” mean the following. We consider a family of objects, with a particular object — an instance of the family — identified by a vector of real parameters (you may think about the family of $n \times n$ square matrices; the vector of parameters in this case is the matrix itself). We say that an instance of the family possesses certain property *in general position*, if the set of values of the parameter vector for which the associated instance does *not* possess the property is of measure 0. Equivalently: randomly perturbing the parameter vector of an instance, the perturbation being uniformly distributed in a (whatever small) box, we with probability 1 get an instance possessing the property in question. E.g., a square matrix “in general position” is nonsingular.

⁵When $s = 5$ and $n = 100$, this number is $\approx 7.53e7$ — much, but perhaps doable. When $n = 200$ and $s = 20$, the number of systems to be processed jumps to $\approx 1.61e27$, which is by many orders of magnitude beyond our “computational grasp”; we would be unable to carry out that many computations even if the fate of the mankind were dependent on them. And from the perspective of Compressed Sensing, $n = 200$ still is a completely toy size, by 3-4 orders of magnitude less than we would like to handle.

where $\text{nnz}(\theta)$ is the number of nonzero entries of a vector θ . At the present level of our knowledge, this problem looks completely intractable (in fact, we do not know algorithms solving the problem essentially faster than the brute force search), and there are strong reasons, to be addressed later in our course, to believe that it indeed is intractable. Well, if we do not know how to minimize under linear constraints the “bad” objective $\text{nnz}(\theta)$, let us “approximate” this objective with one which we do know how to minimize. The true objective is separable: $\text{nnz}(x) = \sum_{i=1}^n \xi(x_i)$, where $\xi(s)$ is the function on the axis equal to 0 at the origin and equal to 1 otherwise. As a matter of fact, the separable functions which we do know how to minimize under linear constraints are sums of convex functions of x_1, \dots, x_n ⁶. The most natural candidate to the role of convex approximation of $\xi(s)$ is $|s|$; with this approximation, (*) converts into the ℓ_1 -minimization problem

$$\min_{\theta} \left\{ \|\theta\|_1 := \sum_{i=1}^n |\theta_i| : X\theta = y \right\}, \quad (1.1.16)$$

which, as we know, is equivalent to the LO program

$$\min_{\theta, w} \left\{ \sum_{i=1}^n w_i : X\theta = y, \theta_i \leq w_i, -\theta_i \leq w_i, 1 \leq i \leq n \right\}.$$

For the time being, we were focusing on the (unrealistic!) case of noiseless observations. A realistic model is that the observation contains noise ξ :

$$y = X\theta + \xi$$

and we know an upper bound ϵ on the “magnitude” $\|\xi\|$ of the noise. In this case, ℓ_1 minimization becomes

$$\min_{\theta} \{ \|\theta\|_1 : \|X\theta - y\| \leq \epsilon \}.$$

When $\|\cdot\|$ is either $\|\cdot\|_{\infty}$, or $\|\cdot\|_1$, the latter problem again reduces to LO, specifically, to the LO program

$$\min_{\theta, w} \left\{ \sum_{j=1}^n w_j : \begin{cases} -\epsilon \leq [X\theta - y]_i \leq \epsilon, 1 \leq i \leq m \\ -w_j \leq x_j \leq w_j, 1 \leq j \leq n \end{cases} \right\}$$

when $\|\cdot\| = \|\cdot\|_{\infty}$, and to the LO program

$$\min_{\theta, w, z} \left\{ \sum_{j=1}^n w_j : \begin{cases} -z_i \leq [X\theta - y]_i \leq z_i, 1 \leq i \leq m \\ \sum_{i=1}^m z_i \leq \epsilon \\ -w_j \leq x_j \leq w_j, 1 \leq j \leq n \end{cases} \right\}$$

when $\|\cdot\| = \|\cdot\|_1$.

***How good is ℓ_1 minimization in the Compressed Sensing context?** Let us say that a sensing matrix X is s -good, if in the noiseless case ℓ_1 minimization recovers correctly all s -sparse “signals” θ . The Compressed Sensing theory demonstrates that

⁶A real-valued function $f(s)$ on the real axis is called *convex*, if its graph, between every pair of its points, is below the chord linking these points, or, equivalently, if $f(x + \lambda(y - x)) \leq f(x) + \lambda(f(y) - f(x))$ for every $x, y \in \mathbf{R}$ and every $\lambda \in [0, 1]$. For example, maxima of (finitely many) affine functions $a_i s + b_i$ on the axis are convex. For more detailed treatment of convexity, see pp 29, 59.

1. For given m, n with $m \ll n$ (say, $m/n \leq 1/2$), there exist $m \times n$ sensing matrices which are s -good for the values of s “nearly as large as m ”, specifically, for $s \leq O(1) \frac{m}{\ln(n/m)}$.⁷ Moreover, there are natural families of matrices where this level of goodness “is a rule.” E.g., when drawing an $m \times n$ matrix at random from the Gaussian or the ± 1 distributions (i.e., filling the matrix with independent realizations of a random variable which is either a standard (zero mean, unit variance) Gaussian one, or takes values ± 1 with probabilities 0.5), the result will be s -good, for the outlined value of s , with probability approaching 1 as m and n grow.
2. If a sensing matrix X is s -good and we are applying ℓ_1 minimization to *noisy* observations, the recovering error is bounded by $C(X)\epsilon$, provided that the true signal θ^* is s -sparse. Thus, small noise results in small recovering error.
3. The above results can be considered as a good news. A bad news is, that we do *not* know how to check efficiently, given an s and a sensing matrix X , that the matrix is s -good. Moreover, we do not know an efficient recipe to build, given m , an $m \times 2m$ matrix X^m which is provably s -good for s larger than $O(1)\sqrt{m}$, which is a much smaller “level of goodness” than the one promised by theory for randomly generated matrices.⁸ The “common life” analogy of this pitiful situation would be as follows: you know that with probability at least 0.9, a brick in your wall is made of gold, and at the same time, you do not know how to tell a golden brick from a usual one.⁹
4. There are *necessary and sufficient* (but, unfortunately, difficult to verify!) conditions for a sensing matrix to be s -good, same as *efficiently verifiable sufficient* conditions for s -goodness; all these conditions are closely related to LO. Specifically,

- (a) *A necessary and sufficient condition for X to be s -good is the existence of $\gamma < 1/2$ such that,*

$$\|\theta\|_{s,1} \leq \gamma \|\theta\|_1 \quad \forall \theta \in \text{Ker } X := \{\theta : X\theta = 0\} \quad (!)$$

⁷From now on, $O(1)$ ’s denote positive *absolute constants* – appropriately chosen numbers like 0.5, or 1, or perhaps 100,000. We could, in principle, replace all $O(1)$ ’s by specific numbers; following the standard mathematical practice, we do not do it, partly from laziness, partly because the particular values of these numbers in our context are irrelevant.

⁸Note that the naive algorithm “generate $m \times 2m$ matrices at random until an s -good, with s promised by the theory, matrix is generated” is *not* an efficient recipe, since we do not know how to check s -goodness efficiently.

⁹This phenomenon is met in many other situations. E.g., in 1938 Claude Shannon (1916-2001), “the father of Information Theory,” made (in his M.Sc. Thesis!) a fundamental discovery as follows. Consider a Boolean function of n Boolean variables (i.e., both the function and the variables take values 0 and 1 only); as it is easily seen there are 2^{2^n} function of this type, and every one of them can be computed by a dedicated circuit comprised of “switches” implementing just 3 basic operations AND, OR and NOT (like computing a polynomial can be carried out on a circuit with nodes implementing just two basic operation: addition of reals and their multiplication). The discovery of Shannon was that every Boolean function of n variables can be computed on a circuit with no more than $Cn^{-1}2^n$ switches, where C is an appropriate absolute constant. Moreover, Shannon proved that “nearly all” Boolean functions of n variables require circuits with *at least* $cn^{-1}2^n$ switches, c being another absolute constant; “nearly all” in this context means that the fraction of “easy to compute” functions (i.e., those computable by circuits with less than $cn^{-1}2^n$ switches) among all Boolean functions of n variables goes to 0 as n goes to ∞ . Now, computing Boolean functions by circuits comprised of switches was an important technical task already in 1938; its role in our today life can hardly be overestimated — the outlined computation is nothing but what is going on in a computer. Given this observation, it is not surprising that the Shannon discovery of 1938 was the subject of countless refinements, extensions, modifications, etc., etc. What is still missing, is a *single individual example* of a “difficult to compute” Boolean function: as a matter of fact, all multivariate Boolean functions $f(x_1, \dots, x_n)$ people managed to describe explicitly are computable by circuits with just *linear* in n number of switches!

where $\|\theta\|_{s,1}$ is the sum of the s largest magnitudes of the entries in θ (this is called the “nullspace property”). The relation to LO stems from the derivation of the condition; this derivation follows more or less straightforwardly from the “first principles” of LO, specifically, from the standard necessary and sufficient conditions (to be studied later in our course) for a solution to an LO program to be optimal. The difficulty with this condition is that we do not know how to verify efficiently, unless s is really small, like 1 or 2. To see where the difficulty originates from, you can rewrite (!) equivalently (check equivalence!) in the form

$$\sum_{i \in I} |\theta_i| \leq \gamma \|\theta\|_1 \quad \forall \theta \in \text{Ker } X \quad \forall (I \subset \{1, \dots, n\} : \text{Card}(I) \leq s) \quad (1.1.17)$$

which makes transparent the combinatorial nature of the condition.

- (b) A verifiable sufficient condition for X to be s -good reads: The relation (1.1.17) for sure is satisfied with

$$\gamma = \alpha_s(X) := \inf_{Y \in \mathbf{R}^{m \times n}} \max_{1 \leq j \leq n} \|\text{Col}_j[I - Y^T X]\|_{s,1},$$

where I is the unit matrix and $\text{Col}_j[A]$ stands for j -th column of a matrix A . In particular, the condition

$$\alpha_s(X) < 1/2$$

is sufficient for X to be s -good.

Here the relation to LO stems from the fact that, as we shall see in the next section, computing $\alpha_s(X)$ reduces to solving an explicit LO program.

Note that $\alpha_s(X) \leq s\alpha_1(X)$ (why?), meaning that the outlined verifiable sufficient condition can be weakened to the condition

$$\alpha_1(X) := \inf_{Y \in \mathbf{R}^{m \times n}} \|I - Y^T X\|_\infty < \frac{1}{2s},$$

where $\|A\|_\infty$ stands for the maximum of magnitudes of the entries in a matrix A . With the experience we have at this point, we immediately see that computing $\alpha_1(X)$ reduces to solving an LO program.

***Sparsity-oriented Signal Processing and ℓ_1 minimization, II: Supervised Binary Machine Learning via LP Support Vector Machines.** Imagine that we have a source of *feature vectors* — collections x of n measurements representing, e.g., the results of n medical tests taken from patients, and a patient can be affected, or not affected, by a particular illness. “In reality,” these feature vectors x go along with *labels* y taking values ± 1 ; in our example, the label -1 says that the patient whose test results are recorded in the feature vector x does *not* have the illness in question, while the label $+1$ means that the patient is ill.

We assume that there is certain dependence between the feature vectors and the labels, and our goal is to predict, given a feature vector alone, the value of the label. What we have in our disposal is a *training sample* (x^i, y^i) , $1 \leq i \leq N$ of *examples* (x^i, y^i) where we know both the feature vector and the label; given this sample, we want to build a *classifier* — a function $f(x)$ on the space of feature vectors x taking values ± 1 — which we intend to use to predict, given the value of a new feature vector, the value of the corresponding label. In our example this setup reads: we are given medical records containing both the results of medical tests and the

diagnoses of N patients; given this data, we want to learn how to predict the diagnosis given the results of the tests taken from a new patient.

The simplest predictors we can think about are just the “linear” ones looking as follows. We fix an affine form $z^T x + b$ of a feature vector, choose a positive threshold γ and say that if the value of the form at a feature vector x is “well positive” – is $\geq \gamma$ – then the proposed label for x is $+1$; similarly, if the value of the form at x is “well negative” – is $\leq -\gamma$ –, then the proposed label will be -1 . In the “gray area” $\gamma < z^T x + b < \gamma$ we decline to classify. Noting that the actual value of the threshold is of no importance (to compensate a change in the threshold by certain factor, it suffices to multiply by this factor both z and b , without affecting the resulting classification), we from now on normalize the situation by setting the threshold to the value 1.

Now, we have explained how a linear classifier works, but where from to take it? An intuitively appealing idea is to use the training sample in order to “train” our potential classifier – to choose z and b in a way which ensures correct classification of the examples in the sample. This amounts to solving the system of linear inequalities

$$z^T x^i + b \geq 1 \forall (i \leq N : y^i = +1) \text{ \& } z^T x^i + b \leq -1 \forall (i : y^i = -1),$$

which can be written equivalently as

$$y^i(z_i^T x^i + b) \geq 1 \quad \forall i = 1, \dots, N.$$

Geometrically speaking, we want to find a “stripe”

$$-1 < z^T x + b < 1 \tag{*}$$

between two parallel hyperplanes $\{x : z^T x + b = -1\}$ and $\{x : z^T x + b = 1\}$ such that all “positive examples” (those with the label $+1$) from the training sample are on one side of this stripe, while all negative (the label -1) examples from the sample are on the other side of the stripe. With this approach, it is natural to look for the “thickest” stripe separating the positive and the negative examples. Since the geometric width of the stripe is $\frac{2}{\sqrt{z^T z}}$ (why?), this amounts to solving the optimization program

$$\min_{z, b} \left\{ \|z\|_2 := \sqrt{z^T z} : y^i(z^T x^i + b) \geq 1, 1 \leq i \leq N \right\}; \tag{1.1.18}$$

The latter problem, of course, not necessarily is feasible: it well can happen that it is impossible to separate the positive and the negative examples in the training sample by a stripe between two parallel hyperplanes. To handle this possibility, we can allow for classification errors and to minimize a weighted sum of $\|w\|_2$ and total penalty for these errors. Since the absence of classification penalty at an example (x^i, y^i) in outer context is equivalent to the validity of the inequality $y^i(w^T x^i + b) \geq 1$, the most natural penalty for misclassification of the example is $\max[1 - y^i(z^T x^i + b), 0]$. With this in mind, the problem of building “the best on the training sample” classifier becomes the optimization problem

$$\min_{z, b} \left\{ \|z\|_2 + \lambda \sum_{i=1}^N \max[1 - y^i(z^T x^i + b), 0] \right\}, \tag{1.1.19}$$

where $\lambda > 0$ is responsible for the “compromise” between the width of the stripe (*) and the “separation quality” of this stripe; how to choose the value of this parameter, this is an additional

story we do not touch here. Note that the outlined approach to building classifiers is the most basic and the most simplistic version of what in Machine Learning is called “Support Vector Machines.”

Now, (1.1.19) is *not* an LO program: we know how to get rid of nonlinearities $\max[1 - y^i(w^T x^i + b), 0]$ by adding slack variables and linear constraints, but we cannot get rid from the nonlinearity brought by the term $\|z\|_2$. Well, there are situations in Machine Learning where it makes sense to get rid of this term by “brute force,” specifically, by replacing the $\|\cdot\|_2$ with $\|\cdot\|_1$. The rationale behind this “brute force” action is as follows. The dimension n of the feature vectors can be large, In our medical example, it could be in the range of tens, which perhaps is “not large;” but think about digitalized images of handwritten letters, where we want to distinguish between handwritten letters “A” and “B;” here the dimension of x can well be in the range of thousands, if not millions. Now, it would be highly desirable to design a good classifier with *sparse* vector of weights z , and there are several reasons for this desire. First, intuition says that a good on the training sample classifier which takes into account just 3 of the features should be more “robust” than a classifier which ensures equally good classification of the training examples, but uses for this purpose 10,000 features; we have all reasons to believe that the first classifier indeed “goes to the point,” while the second one adjusts itself to random, irrelevant for the “true classification,” properties of the training sample. Second, to have a good classifier which uses small number of features is definitely better than to have an equally good classifier which uses a large number of them (in our medical example: the “predictive power” being equal, we definitely would prefer predicting diagnosis via the results of 3 tests to predicting via the results of 20 tests). Finally, if it is possible to classify well via a small number of features, we hopefully have good chances *to understand the mechanism of the dependencies between these measured features and the feature which presence/absence we intend to predict* — it usually is much easier to understand interaction between 2-3 features than between 2,000-3,000 of them. Now, the SVMs (1.1.18), (1.1.19) are not well suited for carrying out the outlined *feature selection* task, since minimizing $\|z\|_2$ norm under constraints on z (this is what explicitly goes on in (1.1.18) and implicitly goes on in (1.1.19)¹⁰) typically results in “spread” optimal solution, with many small nonzero components. In view of our “Compressed Sensing” discussion, we could expect that minimizing the ℓ_1 -norm of z will result in “better concentrated” optimal solution, which leads us to what is called “LO Support Vector Machine.” Here the classifier is given by the solution of the $\|\cdot\|_1$ -analogy of (1.1.19), specifically, the optimization problem

$$\min_{z,b} \left\{ \|z\|_1 + \lambda \sum_{i=1}^N \max[1 - y^i(z^T x^i + b), 0] \right\}. \quad (1.1.20)$$

This problem clearly reduces to the LO program

$$\min_{z,b,w,\xi} \left\{ \sum_{j=1}^n w_j + \lambda \sum_{i=1}^N \xi_i : -w_j \leq z_j \leq w_j, 1 \leq j \leq n, \xi_i \geq 0, \xi_i \geq 1 - y^i(z^T x^i + b), 1 \leq i \leq N \right\}. \quad (1.1.21)$$

¹⁰To understand the latter claim, take an optimal solution (z_*, b_*) to (1.1.19), set $\Lambda = \sum_{i=1}^N \max[1 - y^i(z_*^T x^i + b_*), 0]$ and note that (z_*, b_*) solves the optimization problem

$$\min_{z,b} \left\{ \|z\|_2 : \sum_{i=1}^N \max[1 - y^i(z^T x^i + b), 0] \leq \Lambda \right\}$$

(why?).

Concluding remarks. A reader could ask, what is the purpose of training the classifier on the training set of examples, where we from the very beginning know the labels of all the examples? Well, why a classifier which classifies well on the training set should be good at new examples? Well, intuition says that if a simple rule with a relatively small number of “tuning parameters” (as it is the case with a sparse linear classifier) recovers well the labels in examples from a large enough sample, this classifier should have learned something essential about the dependency between feature vectors and labels, and thus should be able to classify well new examples. Machine Learning theory offers a solid probabilistic framework in which “our intuition is right”, so that under assumptions (not too restrictive) imposed by this framework it is possible to establish quantitative links between the size of the training sample, the behavior of the classifier on this sample (quantified by the $\|\cdot\|_2$ or $\|\cdot\|_1$ norm of the resulting z and the value of the penalty for misclassification), and the *predictive power* of the classifier, quantified by the probability of misclassification of a new example; roughly speaking, good behavior of a linear classifier achieved at a large training sample ensures low probability of misclassifying a new example.

1.2 What Can Be Reduced to LO

Looking at the collection of LO models we have presented, we see that mathematical models which finally can be formulated as LO programs *not always* “are born” in this form; we became acquainted with several tricks which, with luck, allow to convert an non-LO optimization problem into an equivalent LO program. This section is devoted to “in-depth” investigating of these tricks.

1.2.1 Preliminaries

We start with several useful, although “philosophical,” remarks. What we are interested in our course is *mathematics* of Linear Optimization, so that the main entities to be considered are specific functions and sets. Say, an LO program is the program of maximizing a linear *function* $c^T x$ over a *polyhedral subset* X of \mathbf{R}^n , that is, over the solution set $\{x \in \mathbf{R}^n : Ax \leq b\}$ of a finite system of nonstrict linear inequalities in n variables x . Now, sets and functions are abstract “mathematical beasts;” the concept of a set is *the* basic mathematical concept which we do *not* define in terms of simpler concepts¹¹; the concept of a function is a derivative of the concept of a set¹², and both these concepts have nothing to do with particular *representations* of these entities; representations are by far not the same as the entities being described. For example, the segment $[-1, 1]$ of the real line is a set, and this set admits various representations, e.g.,

- the representation as a solution set of the system of two linear inequalities $x \geq -1$, $x \leq 1$ in real variable x ,
- the representation as the set of all values taken by the function $\sin(x)$ on the real axis, and countless variety of other representations. Similarly, a linear function $f(x) = x$ on the real

¹¹Whether one believes that the concept of a set is an abstract “derivative” of our experience in thinking of/handling various collections of “physical” entities, or, following Plato, thinks that this concept is a shadow of certain “idea” existing in some ideal sense, no one offers a formal definition of this fundamental concept, just *illustrates* it. Perhaps the best illustration is the famous citation from George Cantor, the founder of Set Theory: “By a “set” we mean any collection M into a whole of definite, distinct objects m (which are called the “elements” of M) of our perception [Anschauung] or of our thought.”

¹²a function f defined on a set X and taking values in a set Y can be identified with its *graph*, which is the subset of $X \times Y$ comprised by pairs $(x, f(x))$; a subset F of $X \times Y$ indeed represents a function, is every $x \in X$ is the first component of *exactly one* pair from F .

axis can be represented as $f(x) = x$, or $f(x) = x + \sin^2(x) + \cos^2(x) - 1$, and in countless variety of other forms. Thus, we should distinguish between sets/functions as abstract “objects of our perceptions and our thoughts” and their *concrete representations*, keeping in mind that a particular “object of our thoughts” admits many different representations. We should distinguish well between properties of an object and properties of its particular representation. For example, the nonemptiness is a property of the set $[-1, 1]$, while the number of linear inequalities (namely, 2) in its representation as the solution set of the system $x \geq -1, x \leq 1$ in real variable x clearly is a property of the representation in question, not of the set, since the same set can be represented as the solution set of a system of, say, 10 linear inequalities (add to the previous system inequalities $x \leq 3, x \leq 4, \dots, x \leq 10$). In a sense, nearly all we intend to do in our course (or, wider, what a significant part of Mathematics is about), is to understand how to derive conclusions on properties of the “abstract beasts” — sets and functions — from representations of these beasts in certain concrete format. This is a highly challenging and highly nontrivial task, even when speaking about such a simple, at a first glance, property as emptiness.¹³

Now, the abstract form of an optimization problem with n real decision variables is minimizing a given real-valued function $f(x)$ over a given feasible set $X \subset \mathbf{R}^n$; LO deals with this abstract problem in the particular case when f is linear, and X is polyhedral, and even in this particular case deals not with this problem *per se*, but with particular *representations* of the entities involved: f as $c^T x$, X as $\{x : Ax \leq b\}$, with explicitly — just by listing the values of the coefficients — given data c, A, b . As it was already mentioned, the “maiden” representation of a problem, the one in which the problem “is born”, not always is the one required by LO; most typically, the initial representation is in the Mathematical Programming form

$$\max_x \{f_0(x) : x \in X = \{x : f_i(x) \leq 0, i = 1, \dots, m\}\} \quad (\text{MP})$$

with explicitly given (analytically or algorithmically) functions f_0, f_1, \dots, f_m . Thus, we need tools allowing (a) to recognize the possibility of translating a representation of the form (MP) in an LO representation, and (b) to implement the translation when its possibility is recognized. Our goal in the rest of this section is to develop a toolbox of this type.

A reader might ask what for all this “scholastics” about the difference between optimization problems and their representations, and why we intend to operate with representations of mathematical entities rather than to work directly with these entities. The answer is very simple: an algorithm (and at the end of the day we want the problem to be processed and thus need algorithms) by its nature cannot work with abstract mathematical entities, only with their representations; to some extent, the same is true for human beings, as can be witnessed by everybody with even a minimal experience in solving mathematical problems, no matter which ones, building proofs or crunching numbers.

1.2.2 Polyhedral Representations of Sets and Functions: Definitions

When converting an optimization problem (MP) with explicitly given objective and the constraints into an equivalent LO program, our goal is twofold: (a) to end up with a linear objective represented as $c^T y$, and (b) to end up with a feasible set represented as $\{y : Ay \leq b\}$ (we write

¹³To illustrate the point: the Great Fermat Theorem merely states that the set with extremely simple representation (quadruples of positive integers x, y, z, p with $p > 2$ satisfying the equation $x^p + y^p = z^p$) possesses an extremely simple property of being empty.

y instead of x , keeping in mind the possibility to augment the original decision variables with slack ones). It is easy to achieve the first goal: to this end it suffices to add a slack variable t and to rewrite (MP) equivalently as

$$\max_{x,t} \{t : t - f_0(x) \leq 0, f_1(x) \leq 0, \dots, f_m(x) \leq 0\};$$

the objective in the resulting problem is linear in the new design vector $[x; t]$, and the constraints are “as explicitly given” as those in the original problem. To save notation, assume that this transformation is done in advance, so that the problem we intend to convert into an LO program from the very beginning is of the form

$$\min_{x \in X} c^T x, X = \{x \in \mathbf{R}^n : f_i(x) \leq 0, 1 \leq i \leq m\}. \quad (1.2.1)$$

Thus assumption “costs nothing” and allows us to focus solely on the constraints and on the feasible set X they define.

Now, our experience with slack variables suggests a good formalization of the informal task “to end up with a feasible set represented as $\{y : Ay \leq b\}$,” specifically, as follows.

Definition 1.2.1 [Polyhedral representation of a set] *A polyhedral representation (p.r.) of a set $X \in \mathbf{R}^n$ is a representation of the form*

$$X = \{x \in \mathbf{R}^n : \exists w \in \mathbf{R}^s : Px + Qw \leq r\}, \quad (1.2.2)$$

i.e., it is a finite system of nonstrict linear inequalities in variables x, w such that $x \in X$ iff x can be extended, by properly chosen w , to a feasible solution of the system.

Geometrically, polyhedral representation of X means the following: we take a set, given by an explicit system $Px + Qw \leq r$ of linear inequalities, in the space of x, w -variables and project this set onto the subspace of x -variables; the system $Px + Qw \leq r$ polyhedrally represents X iff the projection is exactly X .

The role of polyhedral representability in our contexts stems from the following evident fact:

Observation 1.2.1 *Given a polyhedral representation (1.2.2) of a set $X \in \mathbf{R}^n$, we can immediately and straightforwardly convert problem (1.2.1) into an LO program, specifically, into the program*

$$\max_{x,w} \{c^T x : Px + Qw \leq r\}.$$

Example: Let us look at the linear regression problem with ℓ_1 -fit (problem (1.1.14)) which we now rewrite as a problem with linear objective

$$\min_{\tau, \theta} \left\{ \tau : \sum_{i=1}^N |[x^i]^T \theta - y^i| \leq \tau \right\}.$$

The feasible set of this problem admits an immediate polyhedral representation:

$$\left\{ [\theta; \tau] : \sum_{i=1}^N |\theta^T x^i - y^i| \leq \tau \right\} = \{[\theta; \tau] : \exists w : -w_i \leq [x^i]^T \theta - y^i \leq w_i \ i = 1, \dots, N, \sum_{i=1}^N w_i \leq \tau\} \quad (1.2.3)$$

which allows to rewrite the problem equivalently as the LO program

$$\min_{\theta, \tau, w} \left\{ \tau : -w_i \leq [x^i]^T \theta - y^i \leq w_i \ i = 1, \dots, N, \sum_{i=1}^N w_i \leq \tau \right\}. \quad (1.2.4)$$

This is exactly what we did with the problem of interest in the previous section.

Remark. We see that all we need in order to convert an optimization program with linear objective into an LO program is a polyhedral representation of the feasible set X of the problem. This need is easy to satisfy if X is a polyhedral set represented as $\{x : Ax \leq b\}$. A polyhedral representation of a set is something more flexible — now we do not want to represent X as the solution set of a system of linear inequalities, only as a projection of such a solution set onto the space where X lives. At this point, it is unclear whether the second type of representation indeed is more flexible than the first one, that is, we do not know whether the projection of a polyhedral set in certain \mathbf{R}^n onto a linear subspace is or is not polyhedral. The answer is positive:

Theorem 1.2.1 *Every polyhedrally representable set is polyhedral.*

This important theorem can be obtained as a byproduct of the conceptually simple *Fourier-Motzkin elimination scheme*.

Fourier-Motzkin elimination scheme. Let $X = \{x : \exists w : Px + Qw \leq r\}$, that is, X is the projection on the space of x -variables of the polyhedral set $Q = \{[x; w] : Px + Qw \leq r\}$ in the space of x, w -variables. We want to prove that X can be represented as the solution set of a finite system of linear inequalities solely in variables x . Let $w = [w_1; \dots; w_k]$. We start with eliminating from the polyhedral description of X the variable w_k . To this end, let us set $z = [x; w_1; \dots; w_{k-1}]$, so that the system of linear inequalities $Px + Qw \leq r$ can be rewritten in the form

$$a_i^T z + b_i w_k \leq c_i, \quad 1 \leq i \leq m. \quad (S)$$

Let us “color” an inequality of the system in red, if $b_i > 0$, in green if $b_i < 0$, and in white, if $b_i = 0$, and let I_r , I_g and I_w be the sets of indices of red, green and white inequalities, respectively. Every red inequality can be rewritten equivalently as $w_k \leq c_i/b_i - a_i^T z/b_i =: e_i^T z + f_i$, and every green inequality can be rewritten equivalently as $w_k \geq c_i/b_i - a_i^T z/b_i =: e_i^T z + f_i$. It is clear that z can be extended, by a properly chosen w_k , to a feasible solution of (S) iff, first, z satisfies every white inequality and, second, every “red” quantity $e_i^T z + f_i$ (which should be an upper bound on w_k) is \geq every “green” quantity (which should be a lower bound on w_k). In other words, z can be extended to a feasible solution of (S) if and only if z satisfies the system of linear inequalities

$$a_i^T z \leq b_i \forall i \in I_w; e_i^T z + f_i \geq e_j^T z + f_j \quad \forall (i \in I_r, j \in I_g). \quad (S')$$

that is, the projection of Q on the space of the variables x, w_1, \dots, w_{k-1} is the solution set Q' of a finite system of linear inequalities in these variables; note that X is the projection of Q' on the space of x -variables, that is, we have built a polyhedral representation of X using $k - 1$ slack variables w_1, \dots, w_{k-1} . Proceeding in the same fashion, we can eliminate one by one all slack variables, thus ending up with a desired “free of slack variables” polyhedral representation of X .

Note that the Fourier-Motzkin elimination is an algorithm, and we can easily convert this algorithm into a finite algorithm for solving LO programs. Indeed, given a LO program $\max_x \{c^T x : Ax \leq b\}$ with n variables x_1, \dots, x_n and augmenting these variables by a new variable τ , we can rewrite the program equivalently as

$$\max_{y=[\tau; x]} \{\tau : Ax \leq b, \tau - c^T x \leq 0\}. \quad (P)$$

The set of feasible values of τ — those which can be extended by properly chosen x to feasible solutions of (P) — is the projection of the feasible set of (P) on the τ -axis; applying the above elimination scheme, we can represent this set as the set of solutions of a finite system \mathcal{S} of nonstrict linear inequalities *in variable τ alone*. It is immediately seen that the solution set of such a system

- (a) either is empty,
- (b) or is a ray of the form $\tau \leq \beta$,
- (c) or is a nonempty segment $\alpha \leq \tau \leq \beta$,
- (d) or is a ray of the form $\tau \geq \alpha$,
- (e) or is the entire τ -axis.

Given \mathcal{S} , it is easy to recognize which one of these cases actually takes place, and what are the corresponding α and β . In the case of (a), (P) is infeasible, in the cases (d,e) (P) is feasible and unbounded, in the cases (b,c) it is feasible and bounded, β is the optimal value in (P) , and $\tau = \beta$ is a feasible solution to \mathcal{S} . Starting with this solution and using the elimination scheme in a backward fashion, we can augment $\tau = \beta$ by values of the variables x_1, \dots, x_n , one at a time, in such a way that $[\tau = \beta; x_1; \dots; x_n]$ will be feasible (and then optimal) for (P) . Thus, we can identify in finite time the “feasibility status” (infeasible/feasible and unbounded/feasible and bounded) of (P) and point out, also in finite time, an optimal solution, provided that the problem is feasible and bounded.

Note that as a byproduct of our reasoning, we see that our former claim *a feasible and bounded LO program admits an optimal solution* indeed is true.

A bad news is that the outlined finite algorithm for solving LO programs is of purely academic value; as a practical tool, it can handle extremely small problems only, with few (like 2-3) variables and perhaps few tens of constraints. The reason is that every step of the elimination scheme can increase dramatically the number of linear constraints we should handle. Indeed, if the original system (S) has m inequalities, half of them red and half of them green, after eliminating the first slack variable we will get a system of $m_1 = m^2/4$ inequalities, at the second step we can get as many as $m_1^2/4 = m^4/64$ inequalities, and so on; now take $m = 16$ and look what happens after 5 steps of the recurrence $m := m^2/4$.

The fact that a polyhedrally representable set is polyhedral and thus can be represented by a system of linear inequalities not involving slack variables in no sense diminishes the importance of slack variables and polyhedral representations involving these variables. Indeed, the possibility to represent the set of interest as the solution set of a finite system of linear inequalities is not all we are looking for when building LO models; we definitely do not want to handle astronomically many inequalities. In this latter respect, adding slack variables (i.e., passing to general-type polyhedral representations) can result in dramatic reduction in the number of linear inequalities we need to handle as compared to the case when no slack variables are used. E.g., when speaking about linear regression with ℓ_1 fit, we have seen that the problem indeed can be rewritten equivalently as an LO in the original variables θ, τ of (1.2.3), specifically, as the LO (1.1.15). Note, however, that the latter LO has $n + 1$ variables and as many as 2^N constraints, which is astronomically large already for moderate N . In contrast to this, the LO program (1.2.4), while involving “slightly more” variables ($n + N + 1$), has just $2N + 1$ constraints.

What is ahead. Observation 1.2.1 suggests that a good way to understand what can be reduced to LO is to understand how to recognize that a given set is polyhedral and if it is the case, how to point out a polyhedral representation of the set. It does not make sense to pose this question as a formal mathematical problem — we could recognize polyhedrality only by working with certain initial description of the set; we have assumed that this is a description by m “explicitly given” constraints $f_i(x) \leq 0$, but the words “explicitly given” are too vague to allow for well-defined constructions and provable results. Instead, we are about to develop a kind of “calculus” of polyhedral representations, specifically, to indicate basic examples of p.r.’s, augmented by calculus rules which say that such and such operations with polyhedral sets result in a polyhedral set, and a p.r. of this set can be build in such and such fashion from the p.r.’s of the operands. As a result of these developments, we will be able to conclude that a set which is obtained by such and such sequence of operations from such and such “raw materials” is polyhedral, with such and such p.r.¹⁴

One last remark before passing to calculus of polyhedral representability. In optimization, feasible sets usually are given by finite systems of constraints $f_i(x) \leq 0$, that is, as the intersection of *level sets* of several functions¹⁵. In order to catch this phenomenon, it makes sense to introduce the notion of a *polyhedrally representable function* (p.r.f. for short). This notion is a kind of “derivative” of the notion of a polyhedral set, and the corresponding definitions are as follows.

Definition 1.2.2 Let $f(x)$ be a function on \mathbf{R}^n taking real values and the value $+\infty$.

- (i) The domain $\text{Dom } f$ of f is the set of all x where x is finite;
- (ii) The epigraph of f is the set $\text{Epi}(f) = \{[x; \tau] \in \mathbf{R}^n \times \mathbf{R} : x \in \text{dom } f, \tau \geq f(x)\}$;
- (iii) f is called *polyhedrally representable*, if its epigraph $\text{Epi}(f)$ is a polyhedral set, so that for appropriate matrices P, Q and vectors p, r it holds

$$\{[x; \tau] : x \in \text{Dom } f, \tau \geq f(x)\} = \{[x; \tau] : \exists w : Px + \tau p + Qw \leq r\}. \quad (1.2.5)$$

We refer to a polyhedral representation of the epigraph of f as a *polyhedral representation* (p.r.) of f itself.

Observation 1.2.2 A level set $\{x : f(x) \leq a\}$ of a p.r.f. (polyhedrally representable function) f is a polyhedral set, and a p.r. of this set is readily given by a p.r. of the function, specifically, (1.2.5) implies that

$$\{x : f(x) \leq a\} = \{x : [x; a] \in \text{Epi}(f)\} = \{x : \exists w : Px + Qw \leq r - ap\}.$$

¹⁴The outlined course of actions is very typical for Mathematics. We know what a differentiable function is — there is a formal definition of differentiability expressed in terms of a function as a “mathematical beast”, without reference to any particular representation of this beast. This definition, however, does not allow to recognize differentiability even when function is given by an analytic formula of a simple structure (since the formula can contain nonsmooth components which in fact cancel each other, but this cancellation is very difficult to discover), not speaking about the case when the function is given in a more complicated fashion. What we routinely use to establish differentiability and to compute derivatives is the usual calculus, where we start with “raw materials” — elementary functions like \ln , \sin , \exp , etc., where we check differentiability and compute the derivatives “by bare hands,” by checking the definition of this property. We then augment the “raw materials” by calculus rules which explain us when an operation with functions, like multiplication, addition, taking superposition, etc., preserves differentiability and how to express the derivatives of the result via derivatives of the operands, thus getting a key to differentiating a huge spectrum of functions, including quite complicated ones.

¹⁵A level, or a Lebesgue, set of a function f is, by definition, a set of the form $\{x : f(x) \leq a\}$, where a is a real.

Example: Consider the function $f(x) = \|x\|_1 := \sum_{i=1}^n |x_i| : \mathbf{R}^n \rightarrow \mathbf{R}$. This function is polyhedrally representable, e.g., by the p.r.

$$\text{Epi}(f) := \{[x; \tau] : \tau \geq \sum_{i=1}^n |x_i|\} = \{[x; \tau] : \exists w : -w_i \leq x_i \leq w_i, 1 \leq i \leq n, \sum_{i=1}^n w_i \leq \tau\}.$$

Remarks. Two remarks are in order.

A. Partially defined functions. Normally, a scalar function f of n variables is specified by indicating its *domain* – the set where the function is well defined, and by the description of f as a real-valued function in the domain. It is highly convenient to combine both components of such a description in a single description by allowing the function to take “a fictional” value $+\infty$ outside of the actual domain. A reader should not look for something “mystical” in this approach: this is just a convention allowing to save a lot of words. In order to allow for basic operations with partially defined functions, like their addition or comparison, we augment our convention with the following agreements on the arithmetics of the “extended real axis” $\mathbf{R} \cup \{+\infty\}$.

- *Addition:* for a real a , $a + (+\infty) = (+\infty) + (+\infty) = +\infty$.
- *Multiplication by a nonnegative real λ :* $\lambda \cdot (+\infty) = +\infty$ when $\lambda > 0$, and $0 \cdot (+\infty) = 0$.
- *Comparison:* for a real a , $a < +\infty$ (and thus $a \leq +\infty$ as well), and of course $+\infty \leq +\infty$.

As far as operations with $+\infty$ are concerned, our arithmetic is severely incomplete — operations like $(+\infty) - (+\infty)$ and $(-1) \cdot (+\infty)$ remain undefined. Well, we can live with it.

B. Convexity of polyhedral sets and polyhedrally representable functions. A set $X \in \mathbf{R}^n$ is called convex, if whenever two points x, y belong to X , the entire segment $\{x + \lambda(y - x) = (1 - \lambda)x + \lambda y : 0 \leq \lambda \leq 1\}$ belongs to X .

To understand the link between the informal – verbal – and the formal – algebraic – parts of this definition, note that when x, y are two distinct points, then all points $(1 - \lambda)x + \lambda y$ form, geometrically, the line passing through x and y , and the part of this line corresponding to the range $0 \leq \lambda \leq 1$ of λ “starts” at x ($\lambda = 0$) and “ends” at y ($\lambda = 1$) and thus is exactly what is natural to call “the segment linking x, y .” When $x = y$, the above line, same as its part corresponding to the range $0 \leq \lambda \leq 1$ of values of λ , collapses to the singleton $\{x\}$ which again is the only natural candidate to the role of “segment linking x and x .”

A function $f : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ is called convex iff its epigraph is convex, or, which is the same (*check why),

$$\forall(x, y \in \mathbf{R}^n, \lambda \in [0, 1]) : f((1 - \lambda)x + \lambda y) \leq (1 - \lambda)f(x) + \lambda f(y).$$

To complete the terminology, a function f taking values in $\mathbf{R} \cup \{-\infty\}$ is called *concave*, if $-f$ is convex (in this description, and everywhere else, $-(-\infty) = \infty$). In view of this definition, handling concave functions reduces to handling convex ones, and we prefer to stick to this possibility in the sequel. Note that there is no notion “concave set.”

One can immediately verify (do it!) that a polyhedral set is convex, whence a polyhedrally representable function also is convex. It follows that

- lack of convexity makes impossible polyhedral representation of a set/function,

- consequently, operations with functions/sets allowed by “calculus of polyhedral representability” we intend to develop should be convexity-preserving operations.

To illustrate the latter point: taking intersection of two sets and taking maximum or sum of two functions are convexity-preserving operations, and indeed we shall see them in our calculus. In contrast to this, taking union of two sets and taking minima or difference of two functions not necessarily preserve convexity, and we shall not see these operations in our calculus.

1.2.3 Polyhedral Representations of Sets and Functions: Calculus

The “raw materials” in our calculus are really simple:

- “elementary” polyhedral sets are those represented as $X = \{x \in \mathbf{R}^n : a^T x \leq b\}$ (when $a \neq 0$, or, which is the same, the set is nonempty and differs from the entire space, such a set is called *half-space*);
- “elementary” polyhedrally representable functions are just affine functions represented in the standard form

$$f(x) = a^T x + b$$

An affine function indeed is a p.r.f., since its epigraph

$$\{[x; \tau] : \tau \geq f(x)\}$$

is a solution set of a linear inequality in variables x, τ and thus is polyhedral.

Calculus of polyhedral representability: sets. The basic rules here are as follows:

S.1. Taking finite intersections: *If the sets $X_i \subset \mathbf{R}^n$, $1 \leq i \leq k$, are polyhedral, so is their intersection, and a p.r. of the intersection is readily given by p.r.’s of the operands.*

Indeed, if

$$X_i = \{x \in \mathbf{R}^n : \exists w^i : P_i x + Q_i w^i \leq r_i\}, i = 1, \dots, k,$$

then

$$\bigcap_{i=1}^k X_i = \{x : \exists w = [w^1; \dots; w^k] : P_i x + Q_i w^i \leq r_i, 1 \leq i \leq k\},$$

which is a polyhedral representation of $\bigcap_i X_i$.

S.2. Taking direct products. Given k sets $X_i \subset \mathbf{R}^{n_i}$, their *direct product* $X_1 \times \dots \times X_k$ is the set in $\mathbf{R}^{n_1 + \dots + n_k}$ comprised of all block-vectors $x = [x^1; \dots; x^k]$ with blocks x^i belonging to X_i , $i = 1, \dots, k$. E.g., the direct product of k segments $[-1, 1]$ on the axis is the unit k -dimensional box $\{x \in \mathbf{R}^k : -1 \leq x_i \leq 1, i = 1, \dots, k\}$. The corresponding calculus rule is as follows:

If the sets $X_i \subset \mathbf{R}^{n_i}$, $1 \leq i \leq k$, are polyhedral, so is their direct product, and a p.r. of the product is readily given by p.r.’s of the operands.

Indeed, if

$$X_i = \{x^i \in \mathbf{R}^{n_i} : \exists w^i : P_i x^i + Q_i w^i \leq r_i\}, i = 1, \dots, k,$$

then

$$X_1 \times \dots \times X_k = \{x = [x^1; \dots; x^k] : \exists w = [w^1; \dots; w^k] : P_i x^i + Q_i w^i \leq r_i, 1 \leq i \leq k\}.$$

S.3. Taking affine image. If $X \subset \mathbf{R}^n$ is a polyhedral set and $y = Ax + b : \mathbf{R}^n \rightarrow \mathbf{R}^m$ is an affine mapping, then the set $Y = AX + b := \{y = Ax + b : x \in X\} \subset \mathbf{R}^m$ is a polyhedral, with p.r. readily given by the mapping and a p.r. of X .

Indeed, if $X = \{x : \exists w : Px + Qw \leq r\}$, then

$$\begin{aligned} Y &= \{y : \exists [x; w] : Px + Qw \leq r, y = Ax + b\} \\ &= \{y : \exists [x; w] : Px + Qw \leq r, y - Ax \leq b, Ax - y \leq -b\}. \end{aligned}$$

Since Y admits a p.r., Y is polyhedral (Theorem 1.2.1).

Note: This is the point where we see the importance of slack variables (i.e., the advantage of general-type polyhedral representations $X = \{x : \exists w : Px + Qw \leq r\}$ as compared to straightforward ones $X = \{x : Ax \leq b\}$). When taking intersections and direct products of “straightforwardly represented” polyhedral sets, building a straightforward representation of the result is easy; when taking affine image of the set as simple as the k -dimensional unit box, a straightforward representation of the result exists, but is, in general, intractable, since it can require an exponential in k number of linear inequalities.

S.4. Taking inverse affine image. If $X \subset \mathbf{R}^n$ is polyhedral, and $x = Ay + b : \mathbf{R}^m \rightarrow \mathbf{R}^n$ is an affine mapping, then the set $Y = \{y \in \mathbf{R}^m : Ay + b \in X\} \subset \mathbf{R}^m$ is polyhedral, with p.r. readily given by the mapping and a p.r. of X .

Indeed, if $X = \{x : \exists w : Px + Qw \leq r\}$, then

$$Y = \{y : \exists w : P[Ay + b] + Qw \leq r\} = \{y : \exists w : [PA]y + Qw \leq r - Pb\}.$$

S.5. Taking arithmetic sum: If the sets $X_i \subset \mathbf{R}^n$, $1 \leq i \leq k$, are polyhedral, so is their arithmetic sum $X_1 + \dots + X_k := \{x = x_1 + \dots + x_k : x_i \in X_i, 1 \leq i \leq k\}$, and a p.r. of the sum is readily given by p.r.'s of the operands.

Indeed, the arithmetic sum of the sets X_1, \dots, X_k is the image of their direct product under linear mapping $[x^1; \dots; x^k] \mapsto x^1 + \dots + x^k$, and both operations preserve polyhedrality. Here is an explicit p.r. for the sum: if $X_i = \{x : \exists w^i : P_i x + Q_i w^i \leq r_i\}$, $1 \leq i \leq k$, then

$$X_1 + \dots + X_k = \{x : \exists x^1, \dots, x^k, w^1, \dots, w^k : P_i x^i + Q_i w^i \leq r_i, 1 \leq i \leq k, x = \sum_{i=1}^k x^i\},$$

and it remains to replace the vector equality in the right hand side by a system of two opposite vector inequalities.

Calculus of p.r. functions. Here the basic calculus rules read:

F.1. Taking linear combinations with positive coefficients. If $f_i : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ are p.r.f.'s and $\lambda_i > 0$, $1 \leq i \leq k$, then $f(x) = \sum_{i=1}^k \lambda_i f_i(x)$ is a p.r.f., with a p.r. readily given by those of the operands.

Indeed, if $\{[x; \tau] : \tau \geq f_i(x)\} = \{[x; \tau] : \exists w^i : P_i x + \tau p_i + Q_i w^i \leq r_i\}$, $1 \leq i \leq k$, are p.r.'s of f_1, \dots, f_k , then

$$\begin{aligned} \{[x; \tau] : \tau \geq \sum_{i=1}^k \lambda_i f_i(x)\} &= \{[x; \tau] : \exists t_1, \dots, t_k : t_i \geq f_i(x), 1 \leq i \leq k, \sum_i \lambda_i t_i \leq \tau\} \\ &= \{[x; \tau] : \exists t_1, \dots, t_k, w^1, \dots, w^k : P_i x + t_i p_i + Q_i w^i \leq r_i, 1 \leq i \leq k, \sum_i \lambda_i t_i \leq \tau\}. \end{aligned}$$

F.2. Direct summation. If $f_i : \mathbf{R}^{n_i} \rightarrow \mathbf{R} \cup \{+\infty\}$, $1 \leq i \leq k$, are p.r.f.'s, then so is their direct sum

$$f([x^1; \dots; x^k]) = \sum_{i=1}^k f_i(x^i) : \mathbf{R}^{n_1 + \dots + n_k} \rightarrow \mathbf{R} \cup \{+\infty\}$$

and a p.r. for this function is readily given by p.r.'s of the operands.

Indeed, if $\{[x^i; \tau] : \tau \geq f_i(x^i)\} = \{[x^i; \tau] : \exists w^i : P_i x^i + \tau p_i + Q_i w^i \leq r_i\}$, $1 \leq i \leq k$, are p.r.'s of f_i , then

$$\begin{aligned} & \{[x^1; \dots; x^k; \tau] : \tau \geq \sum_{i=1}^k f_i(x^i)\} \\ &= \{[x^1; \dots; x^k; \tau] : \exists t_1, \dots, t_k : t_i \geq f_i(x^i), 1 \leq i \leq k, \sum_i t_i \leq \tau\} \\ &= \{[x^1; \dots; x^k; \tau] : \exists t_1, \dots, t_k, w^1, \dots, w^k : P_i x^i + t_i p_i + Q_i w^i \leq r_i, 1 \leq i \leq k, \sum_i t_i \leq \tau\}. \end{aligned}$$

F.3. Taking maximum. If $f_i : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ are p.r.f.'s, so is their maximum $f(x) = \max[f_1(x), \dots, f_k(x)]$, with a p.r. readily given by those of the operands. In particular, a piecewise linear function $\max[a_1^T x + b_1, \dots, a_m^T x + b_m]$ is a p.r.f.

Indeed, if $\{[x; \tau] : \tau \geq f_i(x)\} = \{[x; \tau] : \exists w^i : P_i x + \tau p_i + Q_i w^i \leq r_i\}$, $1 \leq i \leq k$, then

$$\{[x; \tau] : \tau \geq \max_i f_i(x)\} = \{[x; \tau] : \exists w^1, \dots, w^k : P_i x + \tau p_i + Q_i w^i \leq r_i, 1 \leq i \leq k\}.$$

Note that this rule mirrors the rule on p.r. of the intersection of polyhedral sets, due to $\text{Epi}(\max_i f_i) = \bigcap_i \text{Epi}(f_i)$.

Note that when we reduce a piecewise linear function $f(x) = \max_{1 \leq i \leq m} [a_i^T x + b_i]$ onto a polyhedral set X , that is, form a function

$$f_X(x) = \begin{cases} f(x), & x \in X \\ +\infty, & x \notin X \end{cases} \quad (!)$$

we get a polyhedrally representable function. Indeed, if

$$X = \{x : \exists w : Px + Qw \leq r\},$$

then

$$\text{Epi}(f_X) = \{[x; \tau] : \exists w : Px + Qw \leq r, a_i^T x + b_i \leq \tau, 1 \leq i \leq m\}.$$

In fact, the opposite is true as well: a polyhedrally representable function always is in the form of (!) with a piecewise linear f . To see this, observe that the epigraph $\text{Epi}(g)$ of a polyhedrally representable function $g(x) : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ is a polyhedrally representable, and thus polyhedral, set in $\mathbf{R}^n \times \mathbf{R}$. The system of linear inequalities defining this epigraph cannot be empty, since then $\text{Epi}(g)$ would be the entire $\mathbf{R}^n \times \mathbf{R}$, meaning that $g \equiv -\infty$, which is not the case. We can assume also that the epigraph is nonempty, since otherwise $g \equiv +\infty$, which is nothing but f_X with an empty domain X . Now, the inequalities $a_i^T x + \alpha_i \tau \leq b_i$, $1 \leq i \leq I$, defining $\text{Epi}(G)$ can be split into two groups: those with $\alpha_i = 0$, let it be so for $1 \leq i \leq p$, and those with $\alpha_i \neq 0$, let it be so for $p+1 \leq i \leq q$. We claim that the second group is nonempty, and in all inequalities of this group we have $\alpha_i < 0$. Indeed, if the second group were empty, then, setting

$X = \{x : a_i^T x \leq b_i, 1 \leq i \leq p\}$, we would get a nonempty (along with $\text{Epi}(g)$) polyhedral set in \mathbf{R}^n such that every pair $[x; \tau]$ with $x \in X$ belongs to $\text{Epi}(g)$, meaning that $g = -\infty$ on $X \neq \emptyset$, which is impossible. Now, since $\text{Epi}(g)$ is nonempty, there exists a pair $[\bar{x}; \bar{\tau}] \in \text{Epi}(g)$, meaning that all pairs $[\bar{x}; \tau]$ with $\tau \geq \bar{\tau}$ also belong to $\text{Epi}(g)$ and thus $a_i^T \bar{x} + \alpha_i \tau \leq b_i$ for all $\tau \geq \bar{\tau}$ and $i > p$, which would be impossible were $\alpha_i > 0$. The bottom line is that with $X = \{x : a_i^T x \leq b_i, 1 \leq i \leq p\}$ it holds

$$\text{Epi}(g) = \{[x, \tau] : x \in X, \tau \geq \max_{p+1 \leq i \leq q} [-\alpha_i]^{-1} [a_i^T x - b_i]\},$$

meaning that $g = f_X$ with $f(x) = \max_{p+1 \leq i \leq q} [-\alpha_i]^{-1} [a_i^T x - b_i]$, as claimed.

The fact that a polyhedrally representable function is just a piecewise linear function restricted onto a polyhedral domain does not nullify the usefulness of the notion of a p.r.f. Indeed, similarly to the case of polyhedral sets, a p.r. function $f(x)$ admitting a “compact” p.r. can require astronomically many “pieces” $a_i^T x + b_i$ in a piecewise linear representation $f(x) = \max_i [a_i^T x + b_i]$ (think of $f(x) = \sum_i |x_i|$).

F.4. Affine substitution of argument. *If a function $f(x) : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ is a p.r.f. and $x = Ay + b : \mathbf{R}^m \rightarrow \mathbf{R}^n$ is an affine mapping, then the function $g(y) = f(Ay + b) : \mathbf{R}^m \rightarrow \mathbf{R} \cup \{+\infty\}$ is a p.r.f., with a p.r. readily given by the mapping and a p.r. of f .*

Indeed, if $\{[x; \tau] : \tau \geq f(x)\} = \{[x; \tau] : \exists w : Px + \tau p + Qw \leq r\}$ is a p.r. of f , then

$$\begin{aligned} \{[y; \tau] : \tau \geq f(Ay + b)\} &= \{[y; \tau] : \exists w : P[Ay + b] + \tau p + Qw \leq r\} \\ &= \{[y; \tau] : \exists w : [PA]y + \tau p + Qw \leq r - Pb\}. \end{aligned}$$

Note that this rule mirrors the rule on p.r. of the inverse affine image of a polyhedral set, since $\text{Epi}(f(Ay + b))$ is the inverse image of $\text{Epi}(f)$ under the affine mapping $[y; \tau] \mapsto [Ay + b; \tau]$.

F.5. Theorem on superposition. *Let $f_i(x) : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ be p.r.f.'s, and let $F(y) : \mathbf{R}^m \rightarrow \mathbf{R} \cup \{+\infty\}$ be a p.r.f. which is nondecreasing w.r.t. every one of the variables y_1, \dots, y_m . Then the superposition*

$$g(x) = \begin{cases} F(f_1(x), \dots, f_m(x)), & f_i(x) < +\infty, 1 \leq i \leq m \\ +\infty, & \text{otherwise} \end{cases}$$

of F and f_1, \dots, f_m is a p.r.f., with a p.r. readily given by those of f_i and F .

Indeed, let

$$\begin{aligned} \{[x; \tau] : \tau \geq f_i(x)\} &= \{[x; \tau] : \exists w^i : P_i x + \tau p + Q_i w^i \leq r_i\}, \\ \{[y; \tau] : \tau \geq F(y)\} &= \{[y; \tau] : \exists w : Py + \tau p + Qw \leq r\} \end{aligned}$$

be p.r.'s of f_i and F . Then

$$\begin{aligned} \{[x; \tau] : \tau \geq g(x)\} &\stackrel{(*)}{=} \{[x; \tau] : \exists y_1, \dots, y_m : y_i \geq f_i(x), 1 \leq i \leq m, F(y_1, \dots, y_m) \leq \tau\} \\ &= \{[x; \tau] : \exists y, w^1, \dots, w^m, w : P_i x + y_i p_i + Q_i w^i \leq r_i, 1 \leq i \leq m, Py + \tau p + Qw \leq r\}, \end{aligned}$$

where $(*)$ is due to the monotonicity of F .

Note that if some of f_i , say, f_1, \dots, f_k , are affine, then the superposition theorem remains valid when we require the monotonicity of F w.r.t. the variables y_{k+1}, \dots, y_m only; a p.r. of the superposition in this case reads

$$\begin{aligned} & \{[x; \tau] : \tau \geq g(x)\} \\ &= \{[x; \tau] : \exists y_{k+1}, \dots, y_m : y_i \geq f_i(x), k+1 \leq i \leq m, F(f_1(x), \dots, f_k(x), y_{k+1}, \dots, y_m) \leq \tau\} \\ &= \{[x; \tau] : \exists y_1, \dots, y_m, w^{k+1}, \dots, w^m, w : y_i = f_i(x), 1 \leq i \leq k, \\ & \quad P_i x + y_i p_i + Q_i w^i \leq r_i, k+1 \leq i \leq m, P y + \tau p + Q w \leq r\}, \end{aligned}$$

and the linear equalities $y_i = f_i(x)$, $1 \leq i \leq k$, can be replaced by pairs of opposite linear inequalities.

Note that when taking superposition, some monotonicity requirements on the outer function are natural, since otherwise this operation does *not* preserve convexity (think of superposition of $f(x) = \max[x_1, x_2]$ and $F(y) = -y$).

1.3 *Fast Polyhedral Approximation of the Second Order Cone

We have seen that taking projection onto a subspace can convert a polyhedral set $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ which is “simple” — is defined by a moderate number of linear inequalities — into a polyhedral set Y which is “complex” — its representation in the form $\{y : By \leq b\}$ requires a much larger number of linear inequalities. An example, already known to us, is

$$Y := \{y \in \mathbf{R}^k : \sum_{i=1}^k |y_i| \leq 1\} = \{y \in \mathbf{R}^k : \exists w : -w_i \leq y_i \leq w_i, 1 \leq i \leq k, \sum_{i=1}^k w_i \leq 1\}.$$

Here the left hand side set $Y \subset \mathbf{R}^k$ is represented as the projection onto the y -plane of the set

$$X = \{[y; w] : -w_i \leq y_i \leq w_i, 1 \leq i \leq k, \sum_{i=1}^k w_i \leq 1\}$$

which “lives” in \mathbf{R}^{2k} and is given by $2k+1$ linear inequalities; it can be proved that every representation of Y in the form $\{y : Cy \leq c\}$ requires *at least* 2^k linear inequalities.

Given this observation, a natural question is whether it is possible to approximate well a *non-polyhedral* set Y by the projection \widehat{X} of a “simple” polyhedral set X in higher dimension. The motivation here might be (and, as far as the construction we intend to present, actually was) the desire to approximate well the problems of optimizing a linear objective over Y (which is not an LO program, since Y is non-polyhedral) by the problem of minimizing the same objective over the close to Y set \widehat{X} ; the latter problem reduces to an LO program with the simple polyhedral feasible set X and thus is within the grasp of LO algorithms.

The answer to our question depends, of course, on what is the set Y we want to approximate. We intend to demonstrate that when Y is a n -dimensional ball, the answer to the above answer is affirmative. Specifically, we intend to prove the following

Theorem 1.3.1 [Fast polyhedral approximation of the Second Order cone] *Let*

$$\mathbf{L}^{n+1} = \{[x; \tau] \in \mathbf{R}^n \times \mathbf{R} : \tau \geq \|x\|_2 := \sqrt{x^T x} \leq \tau\}$$

(this set is called the $(n+1)$ -dimensional Second Order (aka Lorentz, or Ice-Cream) cone). For every n and every $\epsilon \in (0, 1/2)$ one can explicitly point out a system

$$Px + \tau p + Qw \leq 0 \quad (1.3.1)$$

of homogeneous linear inequalities in the original variables x , τ and slack variables w such that
— the number $I(n, \epsilon)$ of inequalities in the system is $\leq O(1)n \ln(1/\epsilon)$,
— the number $V(n, \epsilon) = \dim w$ of slack variables in the system is $\leq O(1)n \ln(1/\epsilon)$,
and the projection

$$\widehat{L}^{n+1} = \{[x; \tau] : \exists w : Px + \tau p + Qw \leq 0\} \quad (1.3.2)$$

of the solution set of this system on the space of (x, τ) -variables is in-between the second-order cone and its “ $(1 + \epsilon)$ -extension.”

$$\mathbf{L}^{n+1} := \{[x; \tau] \in \mathbf{R}^n \times \mathbf{R} : \tau \geq \|x\|_2\} \subset \widehat{L}^{n+1} \subset \mathbf{L}_\epsilon^{n+1} = \{[x; \tau] \in \mathbf{R}^n \times \mathbf{R} : (1 + \epsilon)\tau \geq \|x\|_2\}. \quad (1.3.3)$$

To get an impression of the constant factors in the Theorem, look at a sample of values of $I(n, \epsilon)$, $V(n, \epsilon)$:

n	$\epsilon = 10^{-1}$		$\epsilon = 10^{-6}$		$\epsilon = 10^{-14}$	
	$V(n, \epsilon)$	$I(n, \epsilon)$	$V(n, \epsilon)$	$I(n, \epsilon)$	$V(n, \epsilon)$	$I(n, \epsilon)$
4	6	17	31	69	70	148
16	30	83	159	345	361	745
64	133	363	677	1458	1520	3153
256	543	1486	2711	5916	6169	12710
1024	2203	6006	10899	23758	24773	51050

You can see that $V(n, \epsilon) \approx 0.7n \ln \frac{1}{\epsilon}$, $I(n, \epsilon) \approx 2n \ln \frac{1}{\epsilon}$.

Several comments are in order.

A. When $\epsilon = 1.e-17$ or something like, a usual computer cannot distinguish between 1 and $1 + \epsilon$, so that with such an ϵ , \widehat{L}^{n+1} “for all practical purposes” is the same as the Second Order cone \mathbf{L}^{n+1} . On the other hand, with $\epsilon = 1.e-17$ the polyhedral representation of \widehat{L} the numbers of inequality constraints and slack variables in the polyhedral representation of \widehat{L} by the system (1.3.1) are moderate multiples of n (indeed, while 10^{-17} is “really small,” $\ln(10^{17}) \approx 39.1439$ is a quite moderate number).

B. After we know how to build a fast polyhedral approximation of the Second Order cone, we know how to build such an approximation for a Euclidean ball $B_n^R = \{x \in \mathbf{R}^n : \|x\|_2 \leq R\}$. Indeed, from (1.3.3) it follows that the projection \widehat{B}_n^R onto the x -plane of the polyhedral set

$$\{[x; w] : Px + Qw \leq -Rp\}$$

in the space of (x, w) -variables is in-between B_n^R and $B_n^{(1+\epsilon)R}$:

$$B_\tau^R \subset \widehat{B}_n^R \subset B_n^{(1+\epsilon)R}. \quad (1.3.4)$$

C. In principle, there is nothing strange in the fact that a “good” non-polyhedral set Y in \mathbf{R}^n can be approximated, within a whatever accuracy, by a polyhedral set. Such a possibility definitely exists when Y is a closed and bounded convex set, as it is the case with the ball B_n^R .

Let us focus on this case; to simplify notation, w.l.o.g. let us set $R = 1$ and set $B_n = B_n^1$. It is intuitively clear (and indeed is true) that given an $\epsilon > 0$ and taking a dense enough finite “grid” x_1, \dots, x_N on the boundary of B_n , that is, on the unit sphere $S_{n-1} = \{x \in \mathbf{R}^n : \|x\|_2 = 1\}$, the polytope bounded by the tangent to S_{n-1} at x_i hyperplanes $\{x : x_i^T(x - x_i) = 0\}$, $1 \leq i \leq N$, will contain B_n and be contained in $B_n^{1+\epsilon}$. The problem, however, is how many hyperplanes should we take for this purpose, and the answer is as follows: *For every polyhedral set $\hat{B} \subset \mathbf{R}^n$ such that $B_n \subset \hat{B} \subset B_n^{1+\epsilon}$, the number N of linear inequalities in a “straightforward” polyhedral representation $\hat{B} = \{x \in \mathbf{R}^n : Cx \leq c\}$ is at least $\exp\{O(1)n \ln(1/\epsilon)\}$, provided $\epsilon \leq 0.1$.* We see that a “straightforward” approximation of B_n within a fixed accuracy ϵ , say $\epsilon = 0.1$, by a solution set of a system of linear inequalities requires an exponential in n , and thus astronomically large already for moderate n , number of inequalities. In contrast to this, to approximate B_n within the same accuracy by the *projection* onto the space where B_n lives of a solution set of a system of linear inequalities requires just linear in n numbers of inequalities and slack variables.

It is highly instructive (and not difficult) to understand where the exponential in n lower bound on a number N of linear inequalities in a system in variables $x \in \mathbf{R}^n$ with the solution set well approximating B_n comes from. Assume that a polyhedral set $\hat{B} = \{x \in \mathbf{R}^n : a_i^T x \leq b_i, 1 \leq i \leq N\}$, is in-between B_n and $(1 + \epsilon)B_n = B_n^{1+\epsilon}$, where ϵ is not too large, say, $\epsilon \leq 0.1$. W.l.o.g. we can assume that $a_i \neq 0$ and then normalize them to ensure that $\|a_i\|_2 = 1$ for all i , which we assume from now on. Now, b_i should be ≥ 1 , since otherwise the constraint $a_i^T x \leq b_i$ would cut off B_n a nonempty set (due to $\max_{x \in B_n} a_i^T x = \|a_i\|_2 = 1$) and thus the inclusion $B_n \subset \hat{B}_n$ would be impossible. By the same token, if $b_i > 1$, then, replacing it with 1, we do not affect the validity of the inclusion $B_n \subset \hat{B}$ and only decrease \hat{B} , thus preserving the validity of the inclusion $\hat{B} \subset B_n^{1+\epsilon}$. The bottom line is that we lose nothing by assuming that $\hat{B} = \{x \in \mathbf{R}^n : a_i^T x \leq 1, 1 \leq i \leq N\}$, with all a_i being unit vectors.

Now, to say that $\hat{B} := \{x : a_i^T x \leq 1, i \leq N\} \subset B_n^{1+\epsilon}$ is exactly the same as to say that $\tilde{B} := \{x : a_i^T x \leq (1 - \epsilon), i \leq N\} \subset B_n$. Thus, we are in the situation when

$$\tilde{B} \subset B_n \subset \hat{B},$$

so that the boundary S_{n-1} of B_n should be contained in the set $\hat{B} \setminus (\text{int } \tilde{B})$. The latter set is contained in the union, over $i \leq N$, of the “stripes” $P_i = \{x \in \mathbf{R}^n : (1 - \epsilon) \leq a_i^T x \leq 1\}$, whence also

$$S_{n-1} \subset \bigcup_{i=1}^N \overbrace{[P_i \cap S_{n-1}]}^{H_i} \quad (*)$$

Geometrically, H_i is a “spherical hat,” and all these hats are congruent to the set

$$H_\epsilon = \{x \in \mathbf{R}^n : x^T x = 1, x_n \geq 1 - \epsilon\}.$$

Denoting α_ϵ the $(n - 1)$ -dimensional “spherical area” of H_ϵ and by α the area of the entire S_{n-1} and taking into account that H_1, \dots, H_N cover S_{n-1} , we get

$$N\alpha_\epsilon \geq \alpha \Rightarrow N \geq \frac{\alpha}{\alpha_\epsilon} \quad (!)$$

It remains to bound from below the ratio α/α_ϵ . Let us start with bounding α_ϵ from above. The projection of the spherical hat H_ϵ onto the plane $x_n = 0$ is $(n-1)$ -dimensional ball of radius $r = \sqrt{1 - (1-\epsilon)^2} = \sqrt{2\epsilon - \epsilon^2} \leq \sqrt{2\epsilon}$. When ϵ is ≤ 0.1 , this projection, up to a factor $O(1)$, preserves the $(n-1)$ -dimensional volume, so that $\alpha_\epsilon \geq O(1)r^{n-1}\beta_{n-1}$, where β_{n-1} is the $(n-1)$ -dimensional volume of B_{n-1}^1 . Now, the projection of the “northern part” $\{x : x^T x = 1, x_n \geq 0\}$ of S_{n-1} is B_{n-1}^1 , and this projection clearly reduces the $(n-1)$ -dimensional volume; thus, $\alpha \geq 2\beta_{n-1}$. We end up with $N \geq O(1)r^{-n-1} \leq O(1)(2\epsilon)^{-(n-1)/2} \leq \exp\{O(1)n \ln(1/\epsilon)\}$, as claimed.

A rigorous reasoning goes as follows. Assume that $n \geq 3$. Let $\pi/2 - \phi$ be the “altitude angle” of a point e on S_{n-1} , that is, ϕ is the angle between e and the direction of n -th coordinate axis. Then H_ϵ is the set of all points on the unit sphere S_{n-1} for which $\phi \geq \phi_0 = \arcsin(r)$. Denoting by γ_{n-1} the $(n-2)$ -dimensional volume of S_{n-2} , we clearly have $\alpha_\epsilon = \gamma_{n-1} \int_0^{\phi_0} \sin^{n-2}(\phi) d\phi$ and $\alpha = 2\gamma_{n-1} \int_0^{\pi/2} \sin^{n-2}(\phi) d\phi$. It follows that

$$\begin{aligned} \alpha_\epsilon &\leq \gamma_{n-1} \int_0^{\phi_0} \sin^{n-2}(\phi) \frac{\cos(\phi)}{\cos(\phi_0)} d\phi = \gamma_{n-1} (n-1)^{-1} \cos^{-1}(\phi_0) \sin^{n-1}(\phi_0) \\ &= \gamma_{n-1} (n-1)^{-1} \cos^{-1}(\phi_0) r^{n-1} = \gamma_{n-1} (n-1)^{-1} (1-\epsilon)^{-1} r^{n-1} \end{aligned}$$

At the same time, it can be easily checked numerically that $\cos(x) \geq 0.99 \exp\{-x^2/2\}$ when $0 \leq x \leq 0.5$, whence

$$\begin{aligned} \alpha &= 2\gamma_{n-1} \int_0^{\pi/2} \sin^{n-2}(\phi) d\phi = 2\gamma_{n-1} \int_0^{\pi/2} \cos^{n-2}(\phi) d\phi \geq 1.98\gamma_{n-1} \int_0^{1/2} \exp\{-\phi^2(n-2)/2\} d\phi \\ &= 1.98\gamma_{n-1} (n-2)^{-1/2} \int_0^{\frac{1}{2}\sqrt{n-2}} \exp\{-s^2/2\} ds = 1.98\gamma_{n-1} (n-2)^{-1/2} (1+\epsilon_n) \int_0^\infty \exp\{-s^2/2\} ds \\ &= 0.99\sqrt{2\pi}\gamma_{n-1} (n-2)^{-1/2} (1+\epsilon_n), \end{aligned}$$

where $\epsilon_n \rightarrow 0$ as $n \rightarrow \infty$. Thus,

$$N \geq \alpha/\alpha_\epsilon \geq 0.99(1+\epsilon_n)\sqrt{2\pi}(n-2)^{-1/2}(n-1)(1-\epsilon)r^{-(n-1)} \geq 0.99\sqrt{2\pi}(1+\delta_n)\sqrt{n}(2\epsilon)^{-(n-1)/2}$$

with $\delta_n \rightarrow 0$ as $n \rightarrow \infty$. We see that for large n (on a closest inspection, “large” here means $n \geq 10$) it definitely holds $N \geq 2n^{1/2}(2\epsilon)^{-(n-1)/2}$, provided $\epsilon \leq 0.1$. When $n = 100$ and $\epsilon = 0.1$, this lower bound on N is as large as 7.9e35.

D. In fact, it is well known that the Euclidean ball B_n can be easily approximated by the projection of a very simple polyhedral set — just a box — “living” in higher-dimensional space. Specifically, it is not difficult to prove that if $D_N = \{x \in \mathbf{R}^N : \|x\|_\infty \leq 1\}$ is the unit box in \mathbf{R}^N , $N > n$, then a “random projection” of D_N on \mathbf{R}^n is, typically, close to a Euclidean ball in \mathbf{R}^n , with the discrepancy going to 0 as N/n grows. The precise statement is as follows: if $A_{n,N}$ is a random matrix with independent standard (zero mean, unit variance) Gaussian entries and n, N, ϵ are linked by the relation $\epsilon \geq O(1)\sqrt{\frac{n}{N}} \ln\left(\frac{N}{n}\right)$, then, with probability approaching 1 as n grows, the set $A_{n,N}D_N \subset \mathbf{R}^n$ is in-between two concentric Euclidean balls with the ratio of radii $\leq 1 + \epsilon$.

The advantages of the result stated in Theorem 1.3.1 as compared to this well-known fact are twofold: first, the numbers $N - n$ of “slack variables” and $2N$ of inequality constraints in the “ ϵ -accurate” polyhedral approximation of B_n are “nearly” of order of $n\epsilon^{-2}$ (in fact, by a logarithmic in $1/\epsilon$ factor worse), while Theorem 1.3.1 speaks about “much more compact” ϵ -approximate representation of an n -dimensional ball, with the numbers of slack variables and inequality constraints of order of $n \ln(1/\epsilon)$. Second, the construction underlying Theorem 1.3.1 is explicit and thus possesses not only academic, but also a practical value (see below). In contrast to this, in spite of the provable fact that a random projection of a box, under the assumptions of the “random projection” statement, with high probability is close to a ball, no individual examples

of projections with this property are known (cf. the story about sensing matrices with high level of goodness). This being said, it should be mentioned that in the “random projection” approximation of a ball, the polyhedral set we are projecting is centrally symmetric, which is important in certain academic applications. In contrast to this, the construction underlying Theorem 1.3.1 approximates a ball by the projection of a highly asymmetric polyhedral set; whether results similar to those stated in Theorem 1.3.1 can be obtained when projecting a centrally symmetric polyhedral set, this is an interesting open academic problem.

E. Theorem 1.3.1, essentially, says that “for all practical purposes,” a *conic quadratic* optimization problem, that is, an optimization problem P with linear objective and (finitely many) *conic quadratic* constraints, that is, constraints of the generic form

$$\|Ax + b\|_2 \leq c^T x + d \quad (*)$$

is an LO program (a rigorous statement reads “problem P can be approximated *in a polynomial time fashion* by an LO program;” eventually, we shall understand what “polynomial time fashion” means). Indeed, Theorem says that “for all practical purposes” the set $\|u\|_2 \leq \tau$ is polyhedrally representable with an explicit (and “short”) polyhedral representation. But then, by calculus of polyhedral representability, the same is true for the feasible set of $(*)$ (rule on inverse affine image) and thus for the feasible set of P (rule on taking finite intersections), so that P reduces to an LO program.

Now, “expressive abilities” of conic quadratic problems are surprisingly rich. E.g., a quadratic constraint of the form

$$x^T A^T A x \leq b^T x + c$$

is equivalent (check it!) to the conic quadratic constraint

$$\|[2Ax; 1 - b^T x - c]\|_2 \leq 1 + b^T x_c;$$

some constraints which do not look quadratic at all, e.g., the constraints in variables x, t

$$\prod_{i=1}^n x_i^{-\pi_i} \leq \tau, x > 0$$

where $\pi_i > 0$ are rational numbers, or

$$\prod_{i=1}^n x_i^{\pi_i} \geq \tau, x \geq 0$$

where $\pi_i > 0$ are rational numbers and $\sum_i \pi_i \leq 1$ can be reduced, *in a systematic way*, to a system of conic quadratic constraints in the original variables x, τ and additional slack variables. Theorem 1.3.1 states that “for all practical purposes” (or, scientifically, up to a polynomial time approximation) the rich expressive abilities of conic quadratic programs are shared by the usual LO’s.

As a more striking example, consider the exponential function $\exp\{x\}$. The exponent which “lives” in a computer is somehow different from the exponent which lives in our mind: the latter is well-defined and nonzero on the entire real axis. The former makes sense in a moderate segment of values of x : if you ask MATLAB what is $\exp(-800)$, the answer will be 0, and if you ask what is $\exp(800)$, the answer will be $+\infty$. Thus, “for all practical purposes,” the “real life” exponent $\exp\{x\}$ can be considered as the restriction of the “ideal” exponent which lives in our

mind on a finite, and even not very large, segment $-T \leq x \leq T$. Now, for the “ideal” exponent we have

$$\exp\{x\} = (\exp\{2^{-k}x\})^{2^k},$$

and when $|x| \leq T$ and $2^k \gg T$, $\exp\{2^{-k}x\}$ is pretty close to $1 + 2^{-k}x$. It follows that

$$|x| \leq T \Rightarrow \exp\{x\} \approx (1 + 2^{-k}x)^{2^k}.$$

Note that the right hand side function, restricted onto the segment $[-T, T]$ with $T \leq 2^k$, can be expressed via a “short series” of linear and quadratic inequalities and a single linear equation:

$$\begin{aligned} & \{[x; \tau] \in \mathbf{R}^2 : -T \leq x \leq T, \tau \geq (1 + 2^{-k}x)^{2^k}\} \\ &= \left\{ [x; \tau] \in \mathbf{R}^2 : \exists u_0, u_1, \dots, u_k : \begin{array}{l} -T \leq x \leq T, u_0 = 1 + 2^{-k}x, \\ u_0^2 \leq u_1, u_1^2 \leq u_2, \dots, u_{k-1}^2 \leq u_k, u_k \leq \tau \end{array} \right\}. \end{aligned}$$

Now, the quadratic inequality $u^2 \leq v$ in variables u, v , as we already know, can be represented by a conic quadratic constraint and thus, “for all practical purposes,” can be represented by a short system of *linear* constraints in u, v and additional variables. As a result, *the exponent which “lives in a computer” is, for all practical purposes, a polyhedrally representable function.* The precise statement is as follows:

Given $T > 0$ and $\epsilon \in (0, 1)$, one can point out an explicit system of linear inequalities in scalar variables x, τ and additional variables w such that

- *the number of inequalities in the system, same as the dimension of the vector w , are bounded by polynomials in T and $\ln(1/\epsilon)$;*
- *the projection of the solution set of the system on the 2D plane of x, τ -variables is the epigraph $\text{Epi}(f)$ of a function $f(x)$ (which thus is polyhedrally representable) such that $\text{Dom } f = [-T, T]$ and*

$$|x| \leq T \Rightarrow \exp\{x\} \leq f(x) \leq (1 + \epsilon) \exp\{x\}.$$

It follows that when solving a Geometric Programming problem — an optimization problem with linear objective and finitely many constraints of the form

$$\sum_{i=1}^k \exp\{a_i^T x + b_i\} \leq 1 \tag{!}$$

(perhaps augmented by linear constraints), we can “regularize” the problem by replacing every constraint (!) with the system of constraints

$$0 \geq w_i \geq a_i^T x + b_i, w_i \geq -T, \exp\{w_i\} \leq u_i, 1 \leq i \leq k, \sum_{i=1}^k u_i \leq 1 \tag{!!}$$

where w_i are slack variables and T is a once for ever fixed moderate constant (say, $T = 60$). As far as actual computations are concerned, this regularization does not alter the constraint: whenever x can be extended, for a properly chosen w , to a feasible solution of (!!), x is clearly feasible for (!), and “nearly vice versa.” Specifically, assume that x is feasible for (!). Then clearly $a_i^T x + b_i \leq 0$ for all i , so that setting $w_i = \max[-T, a_i^T x + b_i]$, $u_i = \exp\{w_i\}$, we satisfy all constraints in (!!) except for the last of them, $\sum_{i=1}^k u_i \leq 1$. The latter can happen only when

for some i we have $a_i^T x + b_i < -T$, whence $w_i = -T$ and $u_i = \exp\{-T\}$; in other words, we are enforced to make u_i greater than $\exp\{a_i^T x + b_i\}$, which results in $\sum_i u_i > \sum_i \exp\{a_i^T x + b_i\}$ and thus can lead to the former sum being > 1 in spite of the fact that the latter sum is ≤ 1 (since x is feasible for (!)). But the resulting violation of the last constraint in (!) cannot be larger than $k \exp\{-T\}$; with $T = 60$, this violation is $\leq 10^{-26}k$. It follows that even with k as large as 10^9 , a computer cannot tell the difference between the target inequality $\sum_i u_i \leq 1$ and the actually ensured inequality $\sum_i u_i \leq 1 + k \exp\{-T\}$.

We have seen that “numerically speaking,” the regularized problem is the same as the original Geometric Programming program. On the other hand, the only nonlinear constraints in the regularized problem are $\exp\{w_i\} \leq u_i$, and w_i is restricted to sit in $[-T, 0]$. It follows that we can approximate every one of nonlinear constraints, in a polynomial time fashion, by a “short” system of linear inequalities and thus reduce the original Geometric Programming problem to an LO one.

We do not claim that the best way to solve real-world conic quadratic and Geometric Programming problems is to approximate them by LO’s; both these classes of problems admit dedicated theoretically (and to some extent, also practically) efficient solution algorithms which can solve practical problems faster than LO algorithms as applied to the LO approximations of these problems. What is good and what is bad in practice, it depends on the available software. A decade ago, there were no efficient and reliable software for medium-size (few thousands of variables) conic quadratic problems, and Theorem 1.3.1 was a byproduct of attempts to handle these problems with the existing software. Today there exists efficient and reliable software for solving conic quadratic problems, and there is basically no necessity to reduce these problems to LO. As about Geometric Programming, situation is different; say, in the `cvx`¹⁶ package problems of this type are handled via “fast conic quadratic approximation,” which is nothing but the outlined and somehow refined approximate representation of the epigraph of the exponent, restricted onto a segment, by a system of quadratic inequalities. This being said, note that the outlined “fast polyhedral approximation” results are of definite theoretical interest.

Proof of Theorem 1.3.1. Let $\epsilon > 0$ and a positive integer n be given. We intend to build a polyhedral ϵ -approximation of the Second Order cone \mathbf{L}^{n+1} . W.l.o.g. (think why) we may assume that n is an integer power of 2: $n = 2^\kappa$, $\kappa \in \mathbf{N}$.

1⁰ The key: fast polyhedral approximation of \mathbf{L}^3 . Consider the system of linear inequalities in variables y_1, y_2, y_3 and additional variables ξ^j, η^j , $0 \leq j \leq \nu$ (ν is a parameter of the construction) as follows:

$$\begin{aligned}
 (a) \quad & \begin{cases} \xi^0 & \geq |y_1| \\ \eta^0 & \geq |y_2| \end{cases} \\
 (b) \quad & \begin{cases} \xi^j & = \cos\left(\frac{\pi}{2^{j+1}}\right) \xi^{j-1} + \sin\left(\frac{\pi}{2^{j+1}}\right) \eta^{j-1} \\ \eta^j & \geq \left| -\sin\left(\frac{\pi}{2^{j+1}}\right) \xi^{j-1} + \cos\left(\frac{\pi}{2^{j+1}}\right) \eta^{j-1} \right| \end{cases}, \quad j = 1, \dots, \nu \\
 (c) \quad & \begin{cases} \xi^\nu & \leq y_3 \\ \eta^\nu & \leq \tan\left(\frac{\pi}{2^{\nu+1}}\right) \xi^\nu \end{cases}
 \end{aligned} \tag{1.3.5}$$

Note that (1.3.5) can be straightforwardly rewritten equivalently as a system of linear homogeneous inequalities

$$\Pi^{(\nu)}[y; w] \leq 0 \tag{S_\nu}$$

¹⁶<http://stanford.edu/~boyd/cvx/>

Figure 1.1: From $P = [\xi^j; \eta^j]$ to $P^+ = [\xi^{j+1}; \eta^{j+1}]$: 1) Q is obtained from P by rotation by the angle $\pi/2^{j+2}$; 2) Q' is the reflection of Q w.r.t. the abscissa axis; 3) P^+ is a point on the line QQ' above both Q and Q' .

in variables $y \in \mathbf{R}^3$ and additional variables w , specifically, as follows. First, we add slack variables and associated linear constraints to eliminate the nonlinearities $|\cdot|$ which are present in (a) and in (b); second, we use the equality constraints in (b) to eliminate the variables ξ^j , $1 \leq j \leq \nu$. The numbers of variables and linear inequalities in the resulting system (S_ν) clearly are $\leq O(1)\nu$. (S_ν) is a p.r. of the polyhedral set

$$Y^\nu = \{y \in \mathbf{R}^3 : \exists w : \Pi^{(\nu)}[y; w] \leq 0\}.$$

Lemma 1.3.1 Y^ν is a polyhedral $\chi(\nu)$ -approximation of $\mathbf{L}^3 = \{y \in \mathbf{R}^3 : y_3 \geq \sqrt{y_1^2 + y_2^2}\}$:

$$\mathbf{L}^3 \subset Y^\nu \subset \mathbf{L}_{\delta(\nu)}^3 := \{y \in \mathbf{R}^3 : (1 + \chi(\nu))y_3 \geq \sqrt{y_1^2 + y_2^2}\} \quad (1.3.6)$$

with

$$\chi(\nu) = \frac{1}{\cos\left(\frac{\pi}{2^{\nu+1}}\right)} - 1. \quad (1.3.7)$$

Proof. We should prove that

- (i) If $y \in \mathbf{L}^3$, then y can be extended to a solution to (1.3.5);
- (ii) If $y \in \mathbf{R}^3$ can be extended to a solution to (1.3.5), then $\|[y_1; y_2]\|_2 \leq (1 + \chi(\nu))y_3$.

Let $P_j = [\xi^j; \eta^j]$, $0 \leq j \leq \nu$. System (1.3.5) can be considered as a set of geometric constraints on the points $[y_1; y_2]$, P_0, \dots, P_ν on the 2D plane, namely, as follows (in the story below, we treat x_1 as the abscissa, and x_2 as the ordinate on the 2D plane where the points live):

- (a) says that P_0 should belong to the first quadrant, and its coordinates should be \geq the magnitudes of the respective coordinates in $[y_1; y_2]$.

- (b) says that the link between P_j and P_{j+1} should be as follows (see figure 1.1):
 - given $P = P_j$, we rotate the vector P_j clockwise by the angle $\pi/2^{j+2}$ and then reflect the resulting point w.r.t. the x_1 -axis, thus getting a pair of symmetric w.r.t. this axis pair of points $Q = Q_j$, $Q' = Q'_j$;
 - $P^+ = P_{j+1}$ is a point on the vertical line passing through Q, Q' which is above both these points (i.e., the ordinate of P^+ is \geq the ordinates of Q and of Q').
- (c) says that the point P_ν should belong to the triangle $\Delta = \{0 \leq x_i \leq y_3, x_2 \leq \tan(\pi/2^{\nu+1})x_1\}$.

Now observe that from this description it follows that points associated with feasible solution to (1.3.5) satisfy

$$\|[y_1; y_2]\|_2 \leq \|P_0\|_2 \leq \|P_1\|_2 \leq \dots \leq \|P_\nu\|_2 \leq \frac{1}{\cos(\pi/2^{\nu+1})} y_3,$$

which proves (ii). On the other hand, if $y_3 \geq \|[y_1; y_2]\|_2$, then, setting $P_0 = [y_1; y_2]$ and specifying for all j P_{j+1} as either Q_j , or Q'_j , depending on which one of these points has a larger ordinate, we get

$$y_3 \geq \|[y_1; y_2]\|_2 = \|P_0\|_2 = \dots = \|P_\nu\|_2. \quad (!)$$

We claim that what we get in this way is a feasible solution to (1.3.5). This is clearly true when $y_1 = y_2 = 0$; assuming that the latter is not the case, observe that by construction we have satisfied the constraints (1.3.5.a-b). To prove that (1.3.5.c) is satisfied as well, let us look at the arguments ϕ_j of the points P_j (the angles between the direction of the x_1 -axis and the directions of vectors P_j). P_0 lives in the first quadrant, and thus $\phi_0 \leq \pi/2$. Since Q_0 is obtained by rotating P_0 clockwise by the angle $\pi/4$, Q'_0 is symmetric to Q_0 w.r.t. the x_1 -axis and P_1 is the member of the pair Q_0, Q'_0 living in the first quadrant, the argument ϕ_1 of P_1 satisfies $0 \leq \phi_1 \leq \pi/4$. Similar reasoning, applied to P_1 in the role of P_0 , results in $0 \leq \phi_2 \leq \pi/8$, and so on, resulting in $0 \leq \phi_\nu \leq \pi/2^{\nu+1}$. Since P_ν lives in the first quadrant, $\|P_\nu\|_2 \leq y_3$ by (!) and the argument of P_ν is $\leq \pi/2^{\nu+1}$, which combines with the facts that $\|P_\nu\|_2 \leq y_3$ (by (!)) and that P_ν lives in the first quadrant to imply that P_ν belongs to the triangle Δ , that is, (1.3.5.c) does take place. (i) is proved. \square

2⁰. From $n = 2$ to $n = 2^\kappa$. Now we are ready to approximate the Second Order cone

$$\mathbf{L}^{n+1} = \{[x; \tau] \in \mathbf{R}^n \times \mathbf{R} : \tau \geq \sqrt{x_1^2 + \dots + x_n^2}\}$$

where $n = 2^\kappa$. To this end, let us first add to the 2^κ variables $x_i \equiv x_i^0$ (“variables of generation 0”) $2^{\kappa-1}$ variables x_i^1 (“variables of generation 1”), treating x_i^1 as the “child” of variables x_{2i-1}^0, x_{2i}^0 of generation 0, add in the same fashion $2^{\kappa-2}$ variables of generation 2, children of variables of generation 1, and so on, until arriving at two variables of generation $\kappa - 1$. By definition, the child of these two variables is $\tau \equiv x_1^\kappa$. Now let us impose on the resulting $2n - 1$ variables x_i^ℓ of all generations the constraints

$$\|[x_{2i-1}^{\ell-1}; x_{2i}^{\ell-1}]\|_2 \leq x_i^\ell, \quad 1 \leq \ell \leq \kappa, \quad 1 \leq i \leq 2^{\kappa-\ell}. \quad (1.3.8)$$

It is clear (look at the case of $n = 4$) that the projection of the solution set of this system on the plane of the original variables $x_i = x_i^0$, τ is nothing but \mathbf{L}^{n+1} . Now let us choose positive integers $\nu_1, \nu_2, \dots, \nu_\kappa$ and approximate the 3-dimensional Second Order cones given by

$$\|[x_{2i-1}^\ell; x_{2i}^\ell]\|_2 \leq x_i^{\ell+1}$$

as explained in Lemma 1.3.1, that is, let us replace every one of the constraints in (1.3.8) by the system of linear inequalities

$$\Pi^{(\nu_\ell)}[x_{2i-1}^{\ell-1}; x_{2i}^{\ell-1}; x_i^\ell; w_i^\ell] \leq 0.$$

As a result, (1.3.8) will be replaced by a system \mathcal{S} of linear inequalities in $2n - 1$ variables x_i^ℓ and additional variables w_i^ℓ . Denoting by $I(\nu)$ and by $V(\nu) + 3$ the number of rows, respectively, columns in the matrix $P^{(\nu)}$ (so that $I(\nu) \leq O(1)\nu$ and $V(\nu) \leq O(1)\nu$), the numbers of variables and constraints in \mathcal{S} are, respectively,

$$\begin{aligned} V &= 2n + 2^{\kappa-1}V(\nu_1) + 2^{\kappa-2}V(\nu_2) + \dots + V(\nu_\kappa) \leq O(1) \sum_{\ell=1}^{\kappa} 2^{\kappa-\ell} \nu_\ell, \\ I &= 2^{\kappa-1}I(\nu_1) + 2^{\kappa-2}I(\nu_2) + \dots + I(\nu_\kappa) \leq O(1) \sum_{\ell=1}^{\kappa} 2^{\kappa-\ell} \nu_\ell. \end{aligned} \quad (1.3.9)$$

Invoking Lemma, it is clear that the projection \widehat{L} of the feasible set of \mathcal{S} onto the space of x, τ -variables satisfies the inclusions in Theorem 1.3.1 with the factor

$$\gamma = (1 + \chi(\nu_1))(1 + \chi(\nu_2)) \dots (1 + \chi(\nu_\kappa))$$

in the role of the desired factor $(1 + \epsilon)$. It remains to choose ν_1, \dots, ν_ℓ in way which ensures that $\gamma \leq 1 + \epsilon$, minimizing under this condition the sum $J := \sum_{\ell=1}^{\kappa} 2^{\kappa-\ell} \nu_\ell$ which, according to (1.3.9), is responsible for the sizes (number of variables and number of constraints) of \mathcal{S} . Setting $\nu_\ell = O(1) \ln(\kappa/\epsilon)$ with appropriately chosen $O(1)$, we get $\chi(\nu_\ell) \leq \epsilon/(2\kappa)$, whence $\gamma \leq 1 + \epsilon$ provided $\epsilon \leq 0.1$. With this choice of ν_ℓ , we get $J \leq O(1)n \ln(\kappa/\epsilon) \leq O(1)n \ln(\ln(n)/\epsilon)$ (recall that $\kappa = \log_2 n$), which, up to replacing $\ln(1/\epsilon)$ with $\ln(\ln(n)/\epsilon)$, is what is stated in Theorem 1.3.1. To get what is announced in the Theorem *exactly*, one needs to carry out the optimization in ν_ℓ more carefully¹⁷; we leave this task to the reader. \square

How it works. Setting $y_3 = 1$ in (S_ν) , we get a system (T_ν) of $n_\nu \leq O(1)\nu$ linear inequalities in variables $y \in \mathbf{R}^2$ and in $m_\nu \leq O(1)\nu$ additional variables in such a way that the projection of the solution set P^ν of this system onto the 2D plane of y -variables “approximates the unit circle B_2 within accuracy $\chi(\nu)$,” meaning that the projection is in-between the unit circle B_2 and its $(1 + \chi(\nu))$ -enlargement $B_2^{1+\chi(\nu)}$. Here we illustrate the related numbers. To get a reference point, note that the perfect n -vertex polygon circumscribed around B_2 approximates B_2 within accuracy

$$\epsilon(n) = \frac{1}{\cos(\pi/n)} - 1 \approx \frac{\pi^2}{2n^2}.$$

- P^3 lives in \mathbf{R}^9 and is given by 12 linear inequalities. Its projection onto 2D plane approximates B_2 within accuracy 5.e-3 (as 16-side perfect polygon).

¹⁷Our current choice of ν_ℓ distributes the overall “budget of inaccuracy” ϵ among all cascades $\ell = 1, \dots, \kappa$ of our approximation scheme equally, and this is clearly nonoptimal. Indeed, the number $2^{\kappa-\ell}$ of 3-dimensional Second Order cones we should approximate in cascade ℓ rapidly decreases as ℓ grows, so that in terms of the total number of linear inequalities in the approximation, it is better to use relatively rough approximations of the 3D cones in cascades with small ℓ and gradually improve the quality of approximation as ℓ grows.

- P^6 lives in \mathbf{R}^{12} and is given by 18 linear inequalities. Its projection onto 2D plane approximates B_2 within accuracy 3.e-4 (as 127-side perfect polygon).
- P^{12} lives in \mathbf{R}^{18} and is given by 30 linear inequalities. Its projection onto 2D plane approximates B_2 within accuracy 7.e-8 (as 8,192-side perfect polygon).
- P^{24} lives in \mathbf{R}^{30} and is given by 54 linear inequalities. Its projection onto 2D plane approximates B_2 within accuracy 4.e-15 (as 34,209,933-side perfect polygon).

Part I

Geometry of Linear Optimization

Lecture 2

Polyhedral Sets and their Geometry

An LO program

$$\text{Opt} = \max_x \{c^T x : Ax \leq b\} \quad (2.0.1)$$

is the problem of maximizing a linear objective over the set

$$X = \{x \in \mathbf{R}^n : Ax \leq b\}$$

given by finitely many non-strict linear inequalities. As we remember, sets of this form are called *polyhedral*, and their geometry plays crucial role in the theory and algorithms of LO. In this lecture, we make the first major step towards understanding the geometry of a polyhedral set; our ultimate goal is to establish the following fundamental result:

Theorem [Structure of a polyhedral set] *A nonempty subset X in \mathbf{R}^n is polyhedral if and only if it can be represented via finitely many “generators” $v_1, \dots, v_I \in \mathbf{R}^n$, $r_1, \dots, r_J \in \mathbf{R}^n$ according to*

$$X = \left\{ x = \sum_{i=1}^I \lambda_i v_i + \sum_{j=1}^J \mu_j r_j : \lambda_i \geq 0, \sum_i \lambda_i = 1; \mu_j \geq 0 \right\}.$$

The statement of Theorem is illustrated on figure 2.1. Eventually it will become clear why this result indeed is crucial, and “on the way” to it we will learn numerous notions and techniques which form the major bulk of the theoretical core of LO.

2.1 Preliminaries: Linear and Affine Subspaces, Convexity

2.1.1 Linear Subspaces

Here we recall some basic facts of Linear Algebra; the reader is supposed to be well acquainted with these facts, so that we just list them.

Linear subspace: definition, examples, “calculus”

Recall that a *linear subspace* of \mathbf{R}^n is a *nonempty* subset L of \mathbf{R}^n which is closed w.r.t. taking linear operations: addition and multiplication by reals. Thus, $L \subset \mathbf{R}^n$ is a linear subspace iff it possesses the following three properties:

- $L \neq \emptyset$

Figure 2.1: From a polyhedral set to its generators and back.

a) a polyhedral set X (area bounded by red border) in \mathbf{R}^2

b) the extreme points v_1, v_2, v_3 of X (vertices of the triangle) and their convex hull $\{\sum_{i=1}^3 \lambda_i v_i : \lambda_i \geq 0, \sum_i \lambda_i = 1\}$ (triangle)

c) the two extreme rays $\{tr_1 : t \geq 0\}$ and $\{tr_2 : t \geq 0\}$ of X

d) to get X back, one sums up the triangle and the conic span $\{\mu_1 r_1 + \mu_2 r_2 : \mu_1, \mu_2 \geq 0\}$ of r_1, r_2 (the angle bounded by rays in c)) which is the recessive cone of X .

- [closedness with respect to additions] Whenever $x, y \in L$, we have $x + y \in L$
- [closedness w.r.t. multiplications by reals] Whenever $x \in L$ and $\lambda \in \mathbf{R}$, we have $\lambda x \in L$.

From closedness w.r.t. additions and multiplications by reals it clearly follows that a linear subspace is closed w.r.t. taking *linear combinations* of its elements: whenever $x_1, \dots, x_k \in L$ and $\lambda_1, \dots, \lambda_k \in \mathbf{R}$, the vector $\sum_{i=1}^k \lambda_i x_i$, called the *linear combination of the vectors x_i with coefficients λ_i* , also belongs to L . Linear subspaces of \mathbf{R}^n are exactly the nonempty subsets of \mathbf{R}^n closed w.r.t. taking linear combinations, with whatever coefficients, of their elements (why?)

Examples of linear subspaces in \mathbf{R}^n :

- the entire \mathbf{R}^n clearly is a linear subspace. This is the largest linear subspace in \mathbf{R}^n : whenever L is a linear subspace, we clearly have $L \subset \mathbf{R}^n$
- the origin $\{0\}$ clearly is a linear subspace. This is the smallest linear subspace in \mathbf{R}^n : whenever L is a linear subspace, we have $\{0\} \subset L$. Indeed, since L is nonempty, there exists $x \in L$, whence $0 = 0 \cdot x \in L$ as well.
- The solution set

$$\{x : Ax = 0\} \quad (2.1.1)$$

of a *homogeneous* system of linear equations with an $m \times n$ matrix A . This set clearly is a linear subspace (check it!). We shall see in a while that every linear subspace in \mathbf{R}^n can be represented in the form of (2.1.1), and, in particular, is a polyhedral set.

“Calculus” of linear subspaces

There are several important operations with linear subspaces:

1. *Taking intersection*: if L_1, L_2 are linear subspaces of \mathbf{R}^n , so is their intersection $L_1 \cap L_2$. In fact, the intersection $\bigcap_{\alpha \in \mathcal{A}} L_\alpha$ of a whatever family $\{L_\alpha\}_{\alpha \in \mathcal{A}}$ of linear subspaces is a linear subspace (check it!)

Note: the union of two linear subspaces L_1, L_2 is *not* a linear subspace, unless one of the subspaces contains the other one (why?)

2. *Taking arithmetic sum*: if L_1, L_2 are linear subspaces in \mathbf{R}^n , so is the set $L_1 + L_2 = \{x = x_1 + x_2 : x_1 \in L_1, x_2 \in L_2\}$ (check it!)
3. *Taking orthogonal complement*: if L is a linear subspace in \mathbf{R}^n , so is its *orthogonal complement* — the set $L^\perp = \{y : y^T x = 0 \forall x \in L\}$ of vectors orthogonal to all vectors from L .
4. *Taking linear image*: if L is a linear subspace in \mathbf{R}^n and A is an $m \times n$ matrix, then the set $AL := \{Ax : x \in L\} \subset \mathbf{R}^m$ — the image of L under the linear mapping $x \mapsto Ax : \mathbf{R}^n \rightarrow \mathbf{R}^m$ — is a linear subspace in \mathbf{R}^m (check it!)
5. *Taking inverse linear image*: if L is a linear subspace in \mathbf{R}^n and A is an $n \times k$ matrix, then the set $A^{-1}L = \{y \in \mathbf{R}^k : Ay \in L\}$ — the inverse image of L under the linear mapping $y \mapsto Ay : \mathbf{R}^k \rightarrow \mathbf{R}^n$ — is a linear subspace in \mathbf{R}^k (check it!)
6. *Taking direct product*: Recall that the direct product $X_1 \times \dots \times X_k$ of sets $X_i \subset \mathbf{R}^{n_i}$, $1 \leq i \leq k$ is the set in $\mathbf{R}^{n_1 + \dots + n_k}$ comprised of all block vectors $x = [x^1; \dots; x^k]$ with blocks $x^i \in X_i$, $1 \leq i \leq k$. When all X_i are linear subspaces, so is their direct product (check it!)

The most important “calculus rules” are the relations

$$\begin{aligned}
 (a) \quad & (L^\perp)^\perp = L \\
 (b) \quad & L \cap L^\perp = \{0\}, \quad L + L^\perp = \mathbf{R}^n \\
 (c) \quad & (L_1 + L_2)^\perp = L_1^\perp \cap L_2^\perp \\
 (d) \quad & (AL)^\perp = (A^T)^{-1}L^\perp, \text{ that is } \{y : y^T Ax = 0 \forall x \in L\} = \{y : A^T y \in L^\perp\} \\
 (e) \quad & (L_1 \times \dots \times L_k)^\perp = L_1^\perp \times \dots \times L_k^\perp
 \end{aligned} \tag{2.1.2}$$

where $L, L_1, L_2 \subset \mathbf{R}^n$ (in (a-d)) and $L_i \subset \mathbf{R}^{n_i}$ (in (e)) are linear subspaces, and A is an arbitrary $m \times n$ matrix.

Comment on (2.1.2.b). Let L be a linear subspace in \mathbf{R}^n . The fact that $L + L^\perp = \mathbf{R}^n$ means that every $x \in \mathbf{R}^n$ can be decomposed as $x = x_L + x_{L^\perp}$ with $x_L \in L$ and $x_{L^\perp} \in L^\perp$; in particular, x_L is orthogonal to x_{L^\perp} . Since $L \cap L^\perp = \{0\}$, the decomposition of x into a sum of two vectors, one from L and one from L^\perp , is unique (check it!), and both x_L and x_{L^\perp} linearly depend on x . The components x_L and x_{L^\perp} of x are called *orthogonal projections of x onto L*

and L^\perp , respectively, and the mapping $x \mapsto x_L$ is called the *orthogonal projector onto L* . Since x_L and x_{L^\perp} are orthogonal, we have the identity

$$\|x\|_2^2 := x^T x = \|x_L\|_2^2 + \|x_{L^\perp}\|_2^2.$$

Linear subspace: linear span, dimension, linear independence, bases

Linear span. For every nonempty set $X \subset \mathbf{R}^n$, the set of all linear combinations, with finitely many terms, of vectors from X is a linear subspace (why?), and this linear subspace (called the *linear span* $\text{Lin}(X)$ of X) is the smallest, w.r.t. inclusion, of the linear subspaces containing X : $\text{Lin}(X)$ is a linear subspace, and

$$X \subset \text{Lin}(X) \subset L$$

whenever L is a linear subspace containing X .

Linear span of an empty set. In the above definition of $\text{Lin}(X)$, $X \subset \mathbf{R}^n$ was assumed to be nonempty. It is convenient to assign with the linear span the empty set as well; *by definition*, $\text{Lin}(\emptyset) = \{0\}$. This definition is in full accordance with the standard convention that a sum with empty set of terms is well-defined and is equal to 0, same as it is consistent with the above claim that $\text{Lin}(X)$ is the smallest linear subspace containing X .

When $L = \text{Lin}(X)$, we say that L is *spanned* (ore, more rigorously, *linearly spanned*) by the set $X \subset \mathbf{R}^n$; thus, a linear subspace L is spanned by a set iff L is exactly the set of all linear combinations of vectors from X (with the convention that a linear combination with empty set of terms is equal to 0).

Linear independence. Recall that a collection x_1, \dots, x_k of vectors from \mathbf{R}^n is called *linearly independent*, if the only linear combination of these vectors equal to 0 is the trivial one – all coefficients are equal to 0:

$$\sum_{i=1}^k \lambda_i x_i = 0 \Rightarrow \lambda_i = 0, i = 1, \dots, k.$$

An equivalent definition (check equivalency!) is that x_1, \dots, x_k are linearly independent if and only if the coefficients in a linear combination of x_1, \dots, x_k are uniquely defined by the value of this combination:

$$\sum_{i=1}^k \lambda_i x_i = \sum_{i=1}^k \mu_i x_i \Leftrightarrow \lambda_i = \mu_i, i = 1, \dots, k.$$

Clearly, an empty (i.e., with $k = 0$) collection of k vectors is linearly independent, and a nonempty linearly independent collection is comprised of distinct and nonzero vectors.

Dimension and bases. A given linear subspace L can be represented as a span of many sets (e.g., $L = \text{Lin}(L)$). The fundamental fact of Linear Algebra is that L always is spanned by a *finite* set of vectors. Given this fact, we immediately conclude that there exist “minimal w.r.t. inclusion finite representations of L as a linear span”, that is, finite collections $\{x_1, \dots, x_k\}$ comprised of k points which linearly span L (i.e., every vector from L is a linear combination of vectors x_1, \dots, x_k), and such that when eliminating from the collection an element, the remaining vectors do *not* span the entire L . The following fundamental fact of Linear Algebra provides us with more details on this subject:

Theorem 2.1.1 *Let L be a linear subspace of \mathbf{R}^n . Then*

(i) *There exist finite collections x_1, \dots, x_k which span L and are “minimal” in this respect (i.e., such that eliminating from the collection one or more elements, the remaining vectors do not span L). All minimal finite collections of vectors spanning L are comprised of distinct from each other nonzero vectors and have the same cardinality, called the dimension of L (notation: $\dim L$), and are called linear bases of L . (ii) A collection x_1, \dots, x_k of k vectors from L is a linear basis in L if and only if this collection possesses one of the following equivalent to each other properties:*

(i.1) *The collection spans L , and the vectors of the collection are linearly independent;*

(i.2) *The vectors x_1, \dots, x_k form a maximal w.r.t. inclusion linearly independent collection of vectors from L , that is, x_1, \dots, x_k are linearly independent, but adding to the collection one more vector x_{k+1} from L yields a linearly dependent collection of vectors;*

(i.3) *Every vector x from L admits exactly one representation as a linear combination of vectors x_1, \dots, x_k , that is, for every x there exists exactly one collection of coefficients $\lambda_1, \dots, \lambda_k$ (called the coordinates of x in the basis x_1, \dots, x_k) such that $x = \sum_{i=1}^k \lambda_i x_i$.*

(iii) *One has $L = \text{Lin}(X)$ for certain X iff L admits a linear basis comprised of vectors from X .*

(iv) *For every $n \times n$ nonsingular matrix A , vectors Ax_1, \dots, Ax_k form a basis in the image $AL = \{Ax : x \in L\}$ of L under the linear mapping $x \mapsto Ax$ iff x_1, \dots, x_k form a basis in L .*

The dimension of a linear subspace satisfies several basic relations:

- (a) $0 \leq \dim L \leq n$
- (b) $L_1 \subset L_2 \Rightarrow \dim L_1 \leq \dim L_2$, the inequality being strict unless $L_1 = L_2$
- (c) $\dim(L_1 + L_2) + \dim(L_1 \cap L_2) = \dim L_1 + \dim L_2$
- (d) $\dim L + \dim L^\perp = n$
- (e) $\dim(AL) \leq \dim L$, with equality when A is square and nonsingular
- (f) $\dim(L_1 \times \dots \times L_k) = \dim L_1 + \dots + \dim L_k$

(2.1.3)

where $L, L_1, L_2 \subset \mathbf{R}^n$ (in (a-e)) and $L_i \subset \mathbf{R}^{n_i}$ (in (f)) are linear subspaces.

Examples: • $\dim \mathbf{R}^n = n$, and \mathbf{R}^n is the only subspace of \mathbf{R}^n of dimension n . Bases in \mathbf{R}^n are exactly the collections of n linearly independent vectors (or, if your prefer, collections of columns of $n \times n$ nonsingular matrices), e.g., the *standard basis* comprised of *basic orths* e_1, \dots, e_n , where e_i has a single nonzero entry, equal to 1, namely, in the position i . The coordinates of $x \in \mathbf{R}^n$ in this standard basis are just the entries of x .

• $\dim \{0\} = 0$, and $\{0\}$ is the only subspace of \mathbf{R}^n of dimension 0. The only basis of $\{0\}$ is the empty set.

• The dimensions of all *proper* (distinct from $\{0\}$ and \mathbf{R}^n) linear subspaces of \mathbf{R}^n are integers ≥ 1 and $\leq n - 1$.

• The dimension of the solution set $L = \{x : Ax = 0\}$ of a system of m linear equations with n variables x is $n - \text{Rank } A$. One way to see it is to note that this solution set is nothing but the orthogonal complement to the linear span of the (transposes of the) rows of A ; the dimension of this span is $\text{Rank}(A)$ (definition of rank), and it remains to use the rule (2.1.3.d).

“Inner” and “outer” description of a linear subspace

We have seen that a linear subspace $L \subset \mathbf{R}^n$ of dimension k can be specified (in fact, in many ways, unless $L = \{0\}$) by a finite set which spans L . This is a kind of an “inner” description of

L : in order to get L , one starts with a finite number of vectors from L and then augments them by all their linear combinations.

There is another, equally universal way to specify a linear subspace: to point out a system of homogeneous linear equations $Ax = 0$ such that the solution set of this system is exactly L :

Proposition 2.1.1 (i) $L \subset \mathbf{R}^n$ is a linear subspace if and only if L is a solution set of a (finite) system of homogeneous linear equations $Ax = 0$; in particular, a linear subspace is a polyhedral set.

(ii) When L is a linear subspace of \mathbf{R}^N , the relation $L = \{x : Ax = 0\}$ holds true if and only if the (transposes of the) rows of A span L^\perp .

Proof. We have already seen that the solution set of a system of homogeneous linear equations in variables $x \in \mathbf{R}^n$ is a linear subspace of \mathbf{R}^n . Now let L be a linear subspace of \mathbf{R}^n . It is immediately seen (check it!) that

(!) If a_1, \dots, a_m span a linear subspace M , then the solution set of the system

$$a_i^T x = 0, \quad i = 1, \dots, m \quad (*)$$

is exactly M^\perp .

It follows that choosing a_1, \dots, a_m to span L^\perp , we get, as a solution set of $(*)$, the linear subspace $(L^\perp)^\perp = L$, where the concluding equality is nothing but (2.1.2.a). Thus, every linear subspace L indeed can be represented as a solution set of $(*)$, provided that m and a_1, \dots, a_m are chosen properly, namely, a_1, \dots, a_m span L^\perp . To see that the latter condition is not only sufficient, but also necessary for the solution set of $(*)$ to be L , note that when $L = \{x : a_i^T x = 0, i = 1, \dots, m\}$, we definitely have $a_i \in L^\perp$, and all which remains to verify is that a_1, \dots, a_m not only belong to L^\perp , but also span this linear subspace. Indeed, let $M := \text{Lin}\{a_1, \dots, a_m\}$. By (!), we have $M^\perp = \{x : a_i^T x = 0, i = 1, \dots, m\} = L$, whence $M = (M^\perp)^\perp = L^\perp$, as claimed. \square

A representation $L = \{x : Ax = 0\}$ of a linear subspace L is a kind of “outer” description of L – one says that in order to get L we should delete from the entire space all points violating one or more constraints in the system $Ax = 0$.

Comments. The fact that a linear subspace admits transparent “inner” and “outer” representations, whatever simple it looks, is crucial: in some situations, these are inner representations which help to understand what is going on, while in other situations “outer” representations do the work. For example, when passing from two linear subspaces L_1, L_2 to their sum $L_1 + L_2$, an inner representation of the result is readily given by inner representations of the operands (since the union of two finite sets, the first spanning L_1 and the second spanning L_2 , clearly spans $L_1 + L_2$); at the same time, there is no equally simple way to get an outer representation of $L_1 + L_2$ from outer representations of the operands L_1, L_2 . When passing from the sum of two subspaces to their intersection $L_1 \cap L_2$, the situation is reversed: the outer representation of $L_1 \cap L_2$ is readily given by those of L_1 and L_2 (put the systems of homogeneous equations specifying L_1 and L_2 into a single system of equations), while there is no equally simple way to build a spanning set for $L_1 \cap L_2$, given spanning sets for L_1 and L_2 . In the sequel, speaking about entities more complicated than linear subspaces (affine spaces and polyhedral sets), we will systematically look for both their “inner” and “outer” descriptions.

2.1.2 Affine Subspaces

Affine subspace: Definition, examples, “calculus”

Definition 2.1.1 [Affine subspace] *A set $M \subset \mathbf{R}^n$ is called affine subspace, if it can be represented as a shift of a linear subspace: for properly chosen linear subspace $L \subset \mathbf{R}^n$ and point $a \in \mathbf{R}^n$ we have*

$$M = a + L := \{x = a + y, y \in L\} = \{x : x - a \in L\}. \quad (2.1.4)$$

It is immediately seen (check it!) that the linear subspace L participating in (2.1.4) is uniquely defined by M , specifically, $L = \{z = x - y : x, y \in M\}$; L is called the linear subspace *parallel* to the affine subspace M . In contrast to L , the shift vector a in (2.1.4) is not uniquely defined by M , and one can use in the role of a an arbitrary point from M (and only from M).

A linear subspace of \mathbf{R}^n is a nonempty subset of \mathbf{R}^n which is closed w.r.t. taking linear combinations of its elements. An affine subspace admits a similar description, with *affine* combinations in the role of just linear ones.

Definition 2.1.2 [Affine combination] *An affine combination of vectors x_1, \dots, x_k is their linear combination $\sum_{i=1}^k \lambda_i x_i$ with unit sum of coefficients: $\sum_{i=1}^k \lambda_i = 1$.*

The characteristic property of affine combinations as compared to plain linear ones is that when all vectors participating in the combination are shifted by the same vector a , the combination itself is shifted by the same vector:

$$\sum_{i=1}^k \lambda_i x_i \text{ is affine combination of } x_1, \dots, x_k \Leftrightarrow \sum_{i=1}^k \lambda_i (x_i + a) = \left(\sum_{i=1}^k \lambda_i x_i \right) + a \forall a.$$

Proposition 2.1.2 *A subset M of \mathbf{R}^n is an affine subspace iff it is nonempty and is closed w.r.t. taking affine combinations of its elements.*

Proof. Assume M is an affine subspace. Then it is nonempty and is representable as $M = a + L$ with L being a subspace. If now $x_i = a + u_i$, $i = 1, \dots, k$, are points from M (so that $u_i \in L$) and $\lambda_1, \dots, \lambda_k$ sum up to 1, then $\sum_{i=1}^k \lambda_i x_i = \sum_{i=1}^k \lambda_i u_i + a$, and $\sum_{i=1}^k \lambda_i u_i \in L$ since L is a linear subspace and $u_i \in L$ for all i . Thus, M is nonempty and is closed w.r.t. taking affine combinations of its elements.

Vice versa, let M be nonempty and closed w.r.t. taking affine combinations of its elements, and let us prove that then M is an affine subspace. Let us fix a point a in M (this is possible, since M is nonempty), and let $L = M - a = \{y - a : y \in M\}$. All we need to prove is that L is a linear subspace, that is, that L is nonempty (which is evident, since $0 = a - a \in L$ due to $a \in M$) and is closed w.r.t. taking linear combinations. Indeed, when $x_1, \dots, x_k \in L$ (that is, $y_i = x_i + a \in M$ for all i) and μ_i are reals, we have $x = \sum_i \mu_i x_i = \sum_i \mu_i (y_i - a) = (1 - \sum_i \mu_i) a + \sum_i \mu_i y_i - a$. Since $a \in M$ and all $y_i \in M$, the combination $y = (1 - \sum_i \mu_i) a + \sum_i \mu_i y_i$ (which clearly has coefficients summing up to 1) is an affine combination of vectors from M and as such belongs to M . We see that $x = y - a$ with certain $y \in M$, that is, $x \in L$. Thus, L indeed is a nonempty subset of \mathbf{R}^n closed w.r.t. taking linear combinations of its elements. \square

Exercise 2.1 Proposition 2.1.2 states that a nonempty subset M of \mathbf{R}^n closed w.r.t. taking affine combinations of its elements is an affine subspace. Prove that the conclusion remains true when closedness w.r.t. taking all affine combinations of the elements of M is weakened to closedness with taking only two-term affine combinations $\lambda x + (1 - \lambda)y$ of elements of M . Geometrically: a nonempty subset M of \mathbf{R}^n is an affine subspace if and only if along with every two distinct point $x, y \in M$, M contains the entire line passing through these points.

Examples of affine subspaces in \mathbf{R}^n :

- The entire \mathbf{R}^n is an affine subspace; its parallel linear subspace also is \mathbf{R}^n , and the shift point a can be chosen as any vector;
- A singleton $\{a\}$, with $a \in \mathbf{R}^n$, is an affine subspace; the shift vector is a , the parallel linear subspace is $\{0\}$;
- The solution set of a solvable system of linear equations in variable $x \in \mathbf{R}^n$ is an affine subspace in \mathbf{R}^n :

$$M := \{x : Ax = b\} \neq \emptyset \Rightarrow M \text{ is an affine subspace}$$

Indeed, as Linear Algebra teaches us, “the general solution to a system of linear equations is the sum of its particular solution and the general solution to the corresponding homogeneous system:” is a solves $Ax = b$ and $L = \{x : Ax = 0\}$ is the solution set of the corresponding homogeneous system, then

$$M := \{x : Ax = b\} = a + L,$$

and L is a linear subspace by its origin. Thus, a (nonempty) solution set of a system of linear equations indeed is an affine subspace, with the parallel linear subspace being the solution set of the corresponding homogeneous system.

Note that the reasoning in the latter example can be inverted: if $L = \{x : Ax = 0\}$ and $a \in \mathbf{R}^n$, then $a + L = \{x : Ax = b := Aa\}$, that is, every shift of the solution set of a homogeneous system of linear equations is the set of solutions to the corresponding inhomogeneous system with properly chosen right hand side. Recalling that linear subspaces in \mathbf{R}^n are exactly the same as solution sets of homogeneous systems of linear equations, we conclude that affine subspaces of \mathbf{R}^n are nothing but the solution sets of solvable systems of linear equations in variable $x \in \mathbf{R}^n$, and in particular every affine subspace is a polyhedral set.

“Calculus” of affine subspaces

Some of basic operations with linear subspaces can be extended to affine subspaces, specifically

1. *Taking intersection:* if M_1, M_2 are affine subspaces in \mathbf{R}^n and their intersection is nonempty, this intersection is an affine subspace. Moreover, if $\{M_\alpha\}_{\alpha \in \mathcal{A}}$ is a whatever family of affine subspaces and the set $M = \bigcap_{\alpha \in \mathcal{A}} M_\alpha$ is nonempty, it is an affine subspace.

Indeed, given a family of sets closed w.r.t. certain operation with elements of the set (e.g., taking affine combination of the elements), their intersection clearly is closed w.r.t. the same operation; thus, intersection of an arbitrary family of affine subspaces is closed w.r.t. taking affine combinations of its elements. If, in addition, this intersection is nonempty, then it is an affine subspace (Proposition 2.1.2).

2. *Taking arithmetic sum:* if M_1, M_2 are affine subspaces in \mathbf{R}^n , so is the set $M_1 + M_2 = \{x = x_1 + x_2 : x_1 \in M_1, x_2 \in M_2\}$ (check it!)
3. *Taking affine image:* if M is a linear subspace in \mathbf{R}^n , A is an $m \times n$ matrix and $b \in \mathbf{R}^m$, then the set $AM + b := \{Ax + b : x \in M\} \subset \mathbf{R}^m$ – the image of M under the *affine* mapping $x \mapsto Ax + b : \mathbf{R}^n \rightarrow \mathbf{R}^m$ – is an affine subspace in \mathbf{R}^m (check it!).
In particular, a shift $M + b = \{y = x + b : x \in M\}$ ($b \in \mathbf{R}^n$) of an affine subspace $M \subset \mathbf{R}^n$ is an affine subspace.
4. *Taking inverse affine image:* if M is a linear subspace in \mathbf{R}^n , A is an $n \times k$ matrix, and $b \in \mathbf{R}^n$ and the set $\{y \in \mathbf{R}^k : Ay + b \in M\}$ – the inverse image of L under the affine mapping $y \mapsto Ay + b : \mathbf{R}^k \rightarrow \mathbf{R}^n$ – is nonempty, then this inverse image is an affine subspace in \mathbf{R}^k (check it!)
5. *Taking direct product:* if $M_i \subset \mathbf{R}^{n_i}$ are affine subspaces, $i = 1, \dots, k$, then their direct product $M_1 \times \dots \times M_k$ is an affine subspace in $\mathbf{R}^{n_1 + \dots + n_k}$ (check it!)

Affine subspace: affine span, affine dimension, affine independence, affine bases

Affine span. Recall that the linear span of a set $X \subset \mathbf{R}^n$ is the set comprised of all linear combinations of elements from X , and this is the smallest w.r.t. inclusion linear subspace containing X . Similarly, given a *nonempty* set $X \subset \mathbf{R}^n$, we can form the set $\text{Aff}(X)$ of all *affine* combinations of elements of X . Since affine combination of affine combinations of elements of X is again an affine combination of elements of X (check it!), $\text{Aff}(X)$ is closed w.r.t. taking affine combinations of its elements. Besides this, $\text{Aff}(X) \supset X$, since every $x \in X$ is an affine combination of elements from X : $x = 1 \cdot x$. Thus, $\text{Aff}(X)$ is a nonempty set closed w.r.t. taking affine combinations of its elements and thus is an affine subspace (Proposition 2.1.2). As we have seen, this affine subspace contains X ; it is clear (check it!) that $\text{Aff}(X)$ is the smallest w.r.t. inclusion affine subspace containing X :

$$\emptyset \neq X \subset M, M \text{ is affine subspace} \Rightarrow X \subset \text{Aff}(X) \subset M.$$

The set $\text{Aff}(X)$ is called the *affine span* (or *affine hull*) of X ; we say also that X *affinely spans* an affine subspace M if $M = \text{Aff}(X)$.

As it should be clear in advance, there is a tight relation between linear and affine spans:

Proposition 2.1.3 *Let $\emptyset \neq X \subset \mathbf{R}^n$, and let $a \in X$. Then $\text{Aff}(X) = a + \text{Lin}(X - a)$. In particular, X affinely spans an affine subspace M if and only if $X \in M$ and the set $X - a$, for some (and then — for every) $a \in X$, linearly spans the linear subspace L to which M is parallel.*

Proof. Let $a \in X$. By definition, $\text{Aff}(X)$ is comprised of all vectors representable as $x = \sum_{i=1}^k \lambda_i x_i$ with some k , some $x_i \in X$ and some λ_i with $\sum_i \lambda_i = 1$; for x of the outlined form, we have $x - a = \sum_{i=1}^k \lambda_i (x_i - a)$. In other words, the linear subspace L to which $\text{Aff}(X)$ is parallel (this linear subspace is exactly the set of all differences $x - a$ with $x \in \text{Aff}(X)$) is *exactly* the set of affine combinations of vectors from $X - a$. Since the latter set contains the origin (due to $a \in X$), the set of all *affine* combinations of vectors from $X - a$ is exactly the same as the set $\text{Lin}(X - a)$ of *all linear* combinations of the points from $X - a$ (take a linear combination $\sum_i \mu_i (x_i - a)$ of vectors from $X - a$ and rewrite it as the affine combination $\sum_i \mu_i (x_i - a) + (1 - \sum_i \mu_i)(a - a)$ of

vectors from the same set $X - a$). Thus, $L = \text{Lin}(X - a)$ and therefore $\text{Aff}(X) = a + \text{Lin}(X - a)$ for whatever $a \in X$. \square

Affine independence. Recall that a collection of $k \geq 0$ vectors x_1, \dots, x_k is called linearly independent iff the coefficients of a linear combination of x_1, \dots, x_k are uniquely defined by the value of this combination. The notion of *affine independence* mimics this approach: specifically, a collection of $k + 1$ vectors x_0, \dots, x_k is called *affine independent*, if the coefficients of every *affine* combination of x_0, \dots, x_k are uniquely defined by the value of this combination:

$$\sum_{i=0}^k \lambda_i x_i = \sum_{i=0}^k \mu_i x_i, \sum_i \lambda_i = \sum_i \mu_i = 1 \Rightarrow \lambda_i = \mu_i, 0 \leq i \leq k.$$

Equivalent definition of affine independence (check equivalency!) is: x_0, \dots, x_k are *affinely independent*, if the only linear combination of x_0, \dots, x_k which is equal to 0 and has zero sum of coefficients is the trivial combination:

$$\sum_{i=0}^k \lambda_i x_i = 0, \sum_{i=0}^k \lambda_i = 0 \Rightarrow \lambda_i = 0, 0 \leq i \leq k.$$

As it could be easily guessed, affine independence “reduces” to linear one:

Lemma 2.1.1 *Let $k \geq 0$, and let x_0, \dots, x_k be a collection of $k + 1$ vectors from \mathbf{R}^n . This collection is affinely independent iff the collection $x_1 - x_0, x_2 - x_0, \dots, x_k - x_0$ is linearly independent.*

Proof of Lemma: There is nothing to prove when $k = 0$, since in this case the system of vectors $x_1 - x_0, \dots, x_k - x_0$ is empty and thus is linearly independent, and at the same time the only solution of the system $\sum_{i=0}^0 \lambda_i x_i = 0, \sum_{i=0}^0 \lambda_i = 0$ is $\lambda_0 = 0$. Now let $k \geq 1$. Assuming the vectors $x_1 - x_0, \dots, x_k - x_0$ are linearly dependent, there exists nonzero $\mu = [\mu_1; \dots; \mu_k]$ with $\sum_{i=1}^k \mu_i (x_i - x_0) = 0$, we get a nontrivial solution $\lambda_0 = -\sum_{i=1}^k \mu_i, \lambda_1 = \mu_1, \dots, \lambda_k = \mu_k$ to the system

$$\sum_{i=0}^k \lambda_i x_i = 0, \sum_{i=0}^k \lambda_i = 0 \quad (*)$$

that is, x_0, \dots, x_k are not affinely independent. Vice versa, assuming that x_0, \dots, x_k are not affinely independent, $(*)$ has a nontrivial solution $\lambda_0, \dots, \lambda_k$. Setting $\mu_i = \lambda_i, 1 \leq i \leq k$, and taking into account that $\lambda_0 = -\sum_{i=1}^k \lambda_i$ by the last – the scalar – equality in $(*)$, the first equality in $(*)$ reads $\sum_{i=1}^k \mu_i (x_i - x_0) = 0$. Note that not all $\mu_i = \lambda_i, i = 1, \dots, k$, are zeros (since otherwise we would have also $\lambda_0 = -\sum_{i=1}^k \lambda_i = 0$, that is, $\lambda_0, \dots, \lambda_k$ are zeros, which is not the case). Thus, if x_0, \dots, x_k are not affinely independent, $x_1 - x_0, \dots, x_k - x_0$ are not linearly independent. Lemma is proved. \square

Affine dimension and affine bases. By definition, the *affine dimension* of an affine subspace $M = a + L$ is the linear dimension of the parallel linear subspace L . It is also convenient to define *affine dimension of an arbitrary nonempty set $X \subset \mathbf{R}^n$* as the affine dimension of the affine subspace $\text{Aff}(X)$. In our course, we will not use any other notion of dimension, and therefore from now on, speaking about affine dimension of a set, we shall skip the adjective and call it simply “dimension”.

Remark: The above definitions and convention should be checked for consistency, since with them, some sets (namely, affine subspaces M) are within the scope of *two* definitions of affine dimension: the first definition, applicable to affine subspaces, says that the affine dimension of an affine subspace M is the dimension of the parallel linear subspace, and the second definition, applicable to all nonempty sets, says that the affine dimension of M is the affine dimension of $\text{Aff}(M)$, i.e., is the dimension of the linear subspace parallel to $\text{Aff}(M)$. Fortunately, these two definitions are consistent in the intersection of their scopes: since $M = \text{Aff}(M)$ for an affine subspace M , both definitions of the affine dimension for such an M say the same.

The convention to skip “affine” when speaking about affine dimension could have its own potential dangers, since some sets – specifically, linear subspaces – again are in the scope of two definitions of dimension: the first is the dimension of a linear subspace L (the minimal cardinality of a spanning set of L) and the second is the affine dimension of a nonempty set. Fortunately, here again the definitions coincide in their common scope: affine dimension of a linear subspace L is, by definition, the dimension of the linear subspace parallel to $\text{Aff}(L)$; but for a linear subspace L , $\text{Aff}(L) = L$ and L is the linear subspace parallel to $\text{Aff}(L)$, so that both definitions again say the same.

The bottom line is that we have associated with every *nonempty* subset X of \mathbf{R}^n its *dimension* $\dim X$, which is an integer between 0 and n . For a linear subspace X , the dimension is the cardinality of a minimal finite subset of X which (linearly) spans X or, equivalently, the maximal cardinality of linearly independent subsets of X ; for an affine subspace X , the dimension is the just defined dimension of the linear subspace parallel to X , and for an arbitrary nonempty subset X of \mathbf{R}^n the dimension is the just defined dimension of the affine span $\text{Aff}(X)$ of X . When X is in the scope of more than one definition, all applicable definitions of the dimension are consistent with each other.

Affine bases. Let $M = a + L$ be an affine subspace. We definitely can represent M as $\text{Aff}(X)$ for a nonempty set X (which usually can be chosen in many different ways), e.g., as $M = \text{Aff}(M)$. An immediate corollary of Theorem 2.1.1 and Proposition 2.1.3 is that M can be represented as $\text{Aff}(X)$ for a finite collection $X = \{x_0, \dots, x_k\}$ where $k \geq 0$. Indeed, by Proposition 2.1.3, a necessary and sufficient condition to have $M = \text{Aff}(\{x_0, x_1, \dots, x_k\})$ is $x_0 \in M$ and $\text{Lin}(X - x_0) = L$ (check it!). In order to meet this condition, we can take as x_0 an arbitrary point of M and to select k and a finite set of vectors d_1, \dots, d_k in such a way that this set linearly spans L ; setting $x_i = x_0 + d_i$, $1 \leq i \leq k$, we get a finite set $X = \{x_0, \dots, x_k\}$ which meets the above necessary and sufficient condition and thus affinely spans M . This reasoning clearly can be inverted, leading to the following result:

Proposition 2.1.4 *An affine subspace $M = a + L$ is affinely spanned by a finite set $X = \{x_0, \dots, x_k\}$ if and only if $x_0 \in M$ and the k vectors $x_1 - x_0, x_2 - x_0, \dots, x_k - x_0$ linearly span L . In particular, the minimal in cardinality subsets $X = \{x_0, \dots, x_k\}$ which affinely span M are of cardinality $k + 1 = \dim M + 1$ and are characterized by the inclusion $x_0 \in M$ and the fact that $x_1 - x_0, \dots, x_k - x_0$ is a linear basis in L .*

Note that “in particular” part of the latter statement is readily given by Theorem 2.1.1.

The minimal w.r.t. inclusion collections x_0, x_1, \dots, x_k of vectors from an affine subspace M which affinely span M have a name – they are called *affine bases* of the affine subspace M . It is

a good and easy exercise to combine Proposition 2.1.4, Lemma 2.1.1 and Theorem 2.1.1 to get the following “affine” version of the latter Theorem:

Theorem 2.1.2 *Let M be an affine subspace of \mathbf{R}^n . Then*

(i) *There exist finite collections x_0, \dots, x_k which affinely span M and are “minimal” in this respect (i.e., such that eliminating from the collection one or more elements, the remaining vectors do not affinely span M). All minimal finite collections of vectors affinely spanning M are comprised of distinct vectors from M and have the same cardinality, namely, $\dim M + 1$; these collections are called affine bases of M .*

(ii) *A collection x_0, \dots, x_k of $k + 1$ vectors from M is an affine basis in M if and only if this collection possesses one of the following equivalent to each other properties:*

(ii.1) *The collection affinely spans L , and the vectors of the collection are affinely independent;*

(ii.2) *The vectors x_0, \dots, x_k form a maximal w.r.t. inclusion affinely independent collection of vectors from M , that is, x_0, \dots, x_k are affinely independent, but adding to the collection one more vector x_{k+1} from M yields an affinely dependent collection of vectors;*

(ii.3) *Every vector x from M admits exactly one representation as an affine combination of vectors x_0, \dots, x_k , that is, for every x there exists exactly one collection of coefficients $\lambda_0, \dots, \lambda_k$ (called the affine coordinates of x in the affine basis x_0, \dots, x_k) such that $\sum_{i=0}^k \lambda_i = 1$ and $x = \sum_{i=0}^k \lambda_i x_i$.*

(ii.4) *The vectors $x_1 - x_0, \dots, x_k - x_0$ form a linear basis in the linear subspace L to which M is parallel.*

(iii) *One has $M = \text{Aff}(X)$ for certain X iff M admits an affine basis comprised of vectors from X .*

(iv) *Let A be an $n \times n$ nonsingular matrix. Vectors $Ax_0 + b, \dots, Ax_k + b$ form an affine basis of the image $AM + b = \{y = Ax + b : x \in M\}$ of M under the affine mapping $x \mapsto Ax + b$ iff the vectors x_0, \dots, x_m form an affine basis in M .*

The dimension, restricted onto affine subspaces, satisfies basic relations as follows (cf. (2.1.3)):

- (a) $0 \leq \dim M \leq n$
 - (b) $M_1 \subset M_2 \Rightarrow \dim M_1 \leq \dim M_2$, the inequality being strict unless $M_1 = M_2$
 - (c) if $M_1 \cap M_2 \neq \emptyset$, then $\dim(M_1 + M_2) + \dim(M_1 \cap M_2) = \dim M_1 + \dim M_2$
 - (d) $\dim(AM + b) \leq \dim M$, with equality in the case when A is square and nonsingular,
 - (e) $\dim(M_1 \times \dots \times M_k) = \sum_{i=1}^k \dim(M_i)$,
- (2.1.5)

where M, M_1, M_2, M_i are affine subspaces. Pay attention to the premise $M_1 \cap M_2 \neq \emptyset$ in (c).¹

As about the dimension of arbitrary (nonempty) subsets $X \subset \mathbf{R}^n$, seemingly the only “universal” facts here are as follows (check them!):

- (a) $\emptyset \neq X \subset \mathbf{R}^N \Rightarrow \dim X \in \{0, 1, \dots, n\}$,
 - (b) $\emptyset \neq X \subset Y \subset \mathbf{R}^n \Rightarrow \dim X \leq \dim Y$
- (2.1.6)

¹When $M_1 \cap M_2 = \emptyset$, the conclusion in (c) does not make sense, since the dimension of an empty set is undefined. There are good reasons for it; indeed, when trying to assign an empty set the dimension, we would like to maintain its basic properties, e.g., to ensure the validity of (c) when $M_1 \cap M_2 = \emptyset$, and this clearly is impossible: take two ℓ -dimensional distinct from each other affine subspaces parallel to the same proper linear subspace L of \mathbf{R}^n : $M_1 = L + a$, $M_2 = L + b$, $b \notin M_1$. Then $M_1 \cap M_2 = \emptyset$, $\dim M_1 = \dim M_2 = \dim L$, $\dim(M_1 + M_2) = \dim([a + b] + L) = \dim L$. We see that in order to meet the conclusion in (c), we should have $\dim(\emptyset) + \dim L = 2 \dim L$, i.e., $\dim(\emptyset)$ should be $\dim L$. But the latter quantity depends on what is L , and thus there is no meaningful way to assign \emptyset a dimension.

Examples: • There exists exactly one affine subspace in \mathbf{R}^n of the maximal possible dimension n – this is the entire \mathbf{R}^n . Affine bases in \mathbf{R}^n are of the form $a, a + f_1, \dots, a + f_n$, where $a \in \mathbf{R}^n$ and f_1, \dots, f_n are linearly independent.

• Unless $n = 0$, there exist many affine subspaces of the minimal possible dimension 0; these are singletons $M = \{a\}$, $a \in \mathbf{R}^n$. An affine basis in a singleton $\{a\}$ is comprised of the only vector, namely, a .

• Two types of affine subspaces have special names – *lines* and *hyperplanes*.

— A *line* $\ell \subset \mathbf{R}^n$ is the affine span of two distinct points a, b : $\ell = \{x = (1 - \lambda)a + \lambda b, \lambda \in \mathbf{R}\} = \{x = a + \lambda(b - a), \lambda \in \mathbf{R}\}$. The parallel linear subspace is one-dimensional and is linearly spanned by $b - a$ (same as by the difference of any other pair of two distinct points from the line). Affine bases of ℓ are exactly pairs of distinct points from ℓ .

— A *hyperplane* $\Pi \subset \mathbf{R}^n$ is an affine subspace of dimension $n - 1$, or, equivalently (why?), the solution set of a *single* nontrivial (not all coefficients at the variables are zeros) linear equation $a^T x = b$.

“Inner” and “outer” description of an affine subspace

We have seen that an affine subspace M can be represented (usually, in many ways) as the affine span of a finite collection of vectors x_0, \dots, x_k , that is, represented as the set of all affine combinations of vectors x_0, \dots, x_k . This is an “inner” representation of an affine set M , and the minimal k in such a representation is $\dim M$.

An outer representation of an affine subspace M is its representation as the solution set of a solvable system of linear equations:

$$M = \{x : Ax = b\}. \quad (2.1.7)$$

As we have already seen, such a representation always is possible, and the rows of A in such a representation always linearly span the orthogonal complement L^\perp of the linear subspace L to which M is parallel. The minimal number of equations in a representation (2.1.7) of M is $\dim L^\perp = n - \dim L = n - \dim M$.

2.1.3 Convexity

Linear and affine subspaces of \mathbf{R}^n we have studied so far are polyhedral sets, so that the family of polyhedral sets in \mathbf{R}^n is wider than the family of affine subspaces (which in turn is wider than the family of linear subspaces). The family of *convex sets* in \mathbf{R}^n is, in turn, wider than the family of polyhedral sets, and convexity is, perhaps, the most important property of a polyhedral set. In this section we intend to investigate convexity in more details, the rationale being twofold. First, simple facts we are about to establish play important role in understanding the geometry of polyhedral sets. Second, while polyhedral sets form only a tiny part of the family of convex sets, this “tiny part” is representable: a significant part of the results on polyhedral sets can be extended, sometimes with small modifications, on convex sets. In the sequel, we shall indicate (without proofs) most important of these extensions, thus putting our results on polyhedral sets in a proper perspective.

We have already defined the notion of a convex set and a convex function, and have claimed that all polyhedral sets are convex, leaving the verification of this claim to the reader (see p. 29). For reader’s convenience, we start with reiterating the definitions and proving the above claim.

Definition 2.1.3 (i) Let X be a subset of \mathbf{R}^n . We say that X is convex, if along with every pair x, y of its points, X contains the segment linking these points:

$$\forall(x, y \in X, \lambda \in [0, 1]) : (1 - \lambda)x + \lambda y \in X.$$

(ii) Let $f : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{\infty\}$ be a function. f is called convex if its epigraph – the set

$$\text{Epi}(f) = \{[x; \tau] \in \mathbf{R}^n \times \mathbf{R} : \tau \geq f(x)\}$$

– is convex, or, equivalently (check equivalence!), for all $x, y \in \mathbf{R}^n$ and all $\lambda \in [0, 1]$ it holds

$$f((1 - \lambda)x + \lambda y) \leq (1 - \lambda)f(x) + \lambda f(y) \quad ^2$$

Examples. The most important for our purposes example of a convex set is a polyhedral one:

Proposition 2.1.5 [Convexity of a polyhedral set] Let $X = \{x : Ax \leq b\}$ be a polyhedral set in \mathbf{R}^n . Then X is convex.

Proof. Indeed, let $x, y \in X$ and $\lambda \in [0, 1]$. Then $Ax \leq b$, whence, $A(1 - \lambda)x = (1 - \lambda)Ax \leq (1 - \lambda)b$ due to $\lambda \leq 1$, and $Ay \leq b$, whence $A\lambda y \leq \lambda b$ due to $\lambda \geq 0$. Summing up the vector inequalities $A(1 - \lambda)x \leq (1 - \lambda)b$ and $A\lambda y \leq \lambda b$, we get $A[(1 - \lambda)x + \lambda y] \leq b$. Thus, $(1 - \lambda)x + \lambda y \in X$, and this is so whenever $x, y \in X$ and $\lambda \in [0, 1]$, meaning that X is convex. \square

Corollary 2.1.1 A polyhedrally representable function (see section 1.2.2) is convex.

Indeed, the epigraph of a polyhedrally representable function, by definition of polyhedral representability and by Theorem 1.2.1, is a polyhedral set. \square

Recall that both Proposition 2.1.5 and Corollary 2.1.1 were announced already in Lecture 1.

Of course, there exist non-polyhedral convex sets, e.g., the Euclidean ball $\{x : \|x\|_2^2 \leq 1\}$, same as there exist convex functions which are not polyhedrally representable, e.g., the Euclidean norm $f(x) = \|x\|_2$.³

“Calculus” of convex sets and functions

There are several important convexity-preserving operations with convex sets and convex functions, quite similar to the calculus of polyhedral representability and, as far as sets are concerned, to the calculus of linear/affine subspaces.

²To interpret the value of the right hand side when $f(x)$, or $f(y)$, or both is/are $+\infty$, see the conventions on the arithmetics of the extended real axis on p. 29

³Of course, both the convexity of Euclidean ball in \mathbf{R}^n and the fact that this set is non-polyhedral unless $n = 1$, need to be proved. We, however, can ignore this task – in our course, we are interested in what is polyhedral, and not in what is *not* polyhedral.

Calculus of convex sets. The basic calculus rules are as follows (check their validity!):

1. *Taking intersection:* if X_1, X_2 are convex sets in \mathbf{R}^n , so is their intersection $X_1 \cap X_2$. In fact, the intersection $\bigcap_{\alpha \in \mathcal{A}} X_\alpha$ of a whatever family $\{X_\alpha\}_{\alpha \in \mathcal{A}}$ of convex sets in \mathbf{R}^n is a convex set.
Note: the union of two convex sets most often than not is non-convex.
2. *Taking arithmetic sum:* if X_1, X_2 are convex sets \mathbf{R}^n , so is the set $X_1 + X_2 = \{x = x_1 + x_2 : x_1 \in X_1, x_2 \in X_2\}$.
3. *Taking affine image:* if X is a convex set in \mathbf{R}^n , A is an $m \times n$ matrix, and $b \in \mathbf{R}^m$, then the set $AX + b := \{Ax + b : x \in X\} \subset \mathbf{R}^m$ – the image of X under the affine mapping $x \mapsto Ax + b : \mathbf{R}^n \rightarrow \mathbf{R}^m$ – is a convex set in \mathbf{R}^m .
4. *Taking inverse affine image:* if X is a convex set in \mathbf{R}^n , A is an $n \times k$ matrix, and $b \in \mathbf{R}^n$, then the set $\{y \in \mathbf{R}^k : Ay + b \in X\}$ – the inverse image of X under the affine mapping $y \mapsto Ay + b : \mathbf{R}^k \rightarrow \mathbf{R}^n$ – is a convex set in \mathbf{R}^k .
5. *Taking direct product:* if the sets $X_i \subset \mathbf{R}^{n_i}$, $1 \leq i \leq k$, are convex, so is their direct product $X_1 \times \dots \times X_k \subset \mathbf{R}^{n_1 + \dots + n_k}$.

Calculus of convex functions. The basic rules (check their validity!) are:

1. *Taking linear combinations with positive coefficients:* if functions $f_i : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ are convex and $\lambda_i > 0$, $1 \leq i \leq k$, then the function $f(x) = \sum_{i=1}^k \lambda_i f_i(x)$ is convex.
2. *Direct summation:* if functions $f_i : \mathbf{R}^{n_i} \rightarrow \mathbf{R} \cup \{+\infty\}$, $1 \leq i \leq k$, are convex, so is their direct sum

$$f([x^1; \dots; x^k]) = \sum_{i=1}^k f_i(x^i) : \mathbf{R}^{n_1 + \dots + n_k} \rightarrow \mathbf{R} \cup \{+\infty\}$$

3. *Taking supremum:* the supremum $f(x) = \sup_{\alpha \in \mathcal{A}} f_\alpha(x)$ of a whatever (nonempty) family $\{f_\alpha\}_{\alpha \in \mathcal{A}}$ of convex functions is convex.
4. *Affine substitution of argument:* if a function $f(x) : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ is convex and $x = Ay + b : \mathbf{R}^m \rightarrow \mathbf{R}^n$ is an affine mapping, then the function $g(y) = f(Ay + b) : \mathbf{R}^m \rightarrow \mathbf{R} \cup \{+\infty\}$ is convex.
5. *Theorem on superposition:* Let $f_i(x) : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ be convex functions, and let $F(y) : \mathbf{R}^m \rightarrow \mathbf{R} \cup \{+\infty\}$ be a convex function which is nondecreasing w.r.t. every one of the variables y_1, \dots, y_m . Then the superposition

$$g(x) = \begin{cases} F(f_1(x), \dots, f_m(x)), & f_i(x) < +\infty, 1 \leq i \leq m \\ +\infty, & \text{otherwise} \end{cases}$$

of F and f_1, \dots, f_m is convex.

Note that if some of f_i , say, f_1, \dots, f_k , are affine, then the superposition theorem remains valid when we require the monotonicity of F w.r.t. the variables y_{k+1}, \dots, y_m only.

Convex combinations and convex hull, dimension

A linear subspace is a nonempty set closed w.r.t. taking linear combinations of its elements; an affine subspace is a nonempty set closed with respect to taking affine combinations of its elements. Convex sets in \mathbf{R}^n admit a similar characterization: these are subsets of \mathbf{R}^n (not necessarily nonempty) closed w.r.t. taking *convex combinations* of its elements, where a convex combination of vectors x_1, \dots, x_k is defined as their *linear combination* with *nonnegative coefficients summing up to one*:

$$\sum_{i=1}^k \lambda_i x_i \text{ is a convex combination of } x_i \Leftrightarrow \lambda_i \geq 0, 1 \leq i \leq k, \text{ and } \sum_{i=1}^k \lambda_i = 1.$$

Note that convexity of X , by definition, means closedness of x with respect to taking 2-term convex combinations of its elements. It is an easy and simple exercises to check (do it!) that the following two statements hold true:

Proposition 2.1.6 *A set $X \subset \mathbf{R}^n$ is convex iff this set is closed w.r.t. taking all convex combinations of its elements.*

Corollary 2.1.2 [Jensen's inequality] *If $f : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{\infty\}$ is a convex function, then the value of f at a convex combination of points is \leq the corresponding convex combination of the values of f at the points: whenever $x_1, \dots, x_k \in \mathbf{R}^n$ and $\lambda_i \geq 0, 1 \leq i \leq k$, are such that $\sum_{i=1}^k \lambda_i \leq 1$, one has*

$$f\left(\sum_{i=1}^k \lambda_i x_i\right) \leq \sum_{i=1}^k \lambda_i f(x_i).$$

Jensen's inequality is one of the most useful tools in Mathematics.⁴

Given a set $X \subset \mathbf{R}^n$, we can form a set comprised of all (finite) convex combinations of vectors from X ; this set is called the *convex hull* of X (notation: $\text{Conv}(X)$). Since a convex combination of convex combinations of certain vectors is again a convex combination of these vectors (why?), $\text{Conv}(X)$ is a convex set; invoking Proposition 2.1.6, this is the smallest, w.r.t. inclusion, convex set containing X :

$$X \subset Y, Y \text{ is convex} \Rightarrow X \subset \text{Conv}(X) \subset Y.$$

Dimension. We have already assigned every nonempty subset X of \mathbf{R}^n with dimension, defined as affine dimension of $\text{Aff}(X)$, or, equivalently, as linear dimension of the linear subspace parallel to $\text{Aff}(X)$; in particular, all nonempty convex sets in \mathbf{R}^n are assigned with their dimensions, which are integers from the range $0, 1, \dots, n$. Now, a set X of a large dimension can be very “tiny”; e.g., taking the union of $n + 1$ points affinely spanning \mathbf{R}^n , we get a *finite* set X of dimension n ; clearly, in this case the dimension does not say much about how “massive” is our set (and in fact has nothing in common with topological properties of the set). The situation changes dramatically when the set X is convex; here the dimension, as defined above, quantifies properly the “massiveness” of the set, due to the following result which we shall use on different occasions in the sequel:

⁴A reader could ask how such an easy to prove fact as Jensen's inequality could be that important. Well, it is indeed easy to apply this tool; a nontrivial part of the job, if any, is to prove that the function the inequality is applied to is convex.

Theorem 2.1.3 *Let X be a nonempty convex set in \mathbf{R}^n . Then X has a nonempty interior in its affine span: there exists $\bar{x} \in X$ and $r > 0$ such that*

$$y \in \text{Aff}(X), \|y - \bar{x}\|_2 \leq r \Rightarrow y \in X.$$

In particular, if X is full-dimensional (i.e., $\dim X = n$, or, which is the same, $\text{Aff}(X) = \mathbf{R}^n$), then X contains a Euclidean ball of positive radius.

Proof. Let $M = \text{Aff}(X)$. When $k := \dim M = 0$, we have $X = M = \{a\}$, and we can take $\bar{x} = a$ and, say, $r = 1$. Now let $k > 0$. By Theorem 2.1.2.(iii), we can find a collection x_0, x_1, \dots, x_k of points from X which is an affine basis of M , meaning, by item (ii) of the same Theorem, that every vector from M can be represented, in a unique way, as an affine combination of vectors x_0, \dots, x_k . In other words, the system of linear equations in variables $\lambda_0, \dots, \lambda_k$:

$$\begin{aligned} \sum_{i=0}^k \lambda_i x_i &= x \\ \sum_{i=0}^k \lambda_i &= 1 \end{aligned} \tag{2.1.8}$$

has a solution if and only if $x \in M$, and this solution is unique. Now, Linear Algebra says that in such a situation the solution $\lambda = \lambda(x)$ is a continuous function of $x \in M$. Setting $\bar{x} = \frac{1}{k+1} \sum_{i=0}^k x_i$, the solution is $\lambda(\bar{x}) = [1/(k+1); \dots, 1/(k+1)]$, that is, it is strictly positive; by continuity, there is a neighborhood of positive radius r of \bar{x} in M where the solution is nonnegative:

$$x \in M, \|x - \bar{x}\|_2 \leq r \Rightarrow \lambda(x) \geq 0.$$

Looking at our system, we see that all vectors $x \in M$ for which it has a nonnegative solution are convex combinations of x_0, \dots, x_k and thus belong to X (since X is convex and $x_0, \dots, x_k \in X$). Thus, X indeed contains a neighborhood of \bar{x} in M .

For those who do not remember why “Linear Algebra says...”, here is the reminder. System (2.1.8) is solvable for $x \in M \neq \emptyset$ and the solution is unique, meaning that the matrix $A = [[x_0; 1], \dots, [x_k; 1]]$ of the system has rank $k+1$, and thus we can extract from A $k+1$ rows which form a nonsingular $(k+1) \times (k+1)$ submatrix \hat{A} . In other words, the solution, when it exists, is $\hat{A}^{-1}P(x)$, where $P(x)$ is the part of the right hand side vector $[x; 1]$ in (2.1.8). Thus, the solution $\lambda(x)$ is merely an affine function of $x \in M$, and thus is continuous in $x \in M$. \square

“Inner” and “outer” representations of convex sets

An “inner” representation of a convex set X is its representation as a convex hull: to get X , you should choose appropriately a set $Y \subset \mathbf{R}^n$ (e.g., $Y = X$) and augment it by all convex combinations of elements of Y . While you indeed can get in this fashion a whatever convex set in \mathbf{R}^n , this result is incomparably less useful than its linear/affine subspace counterparts known to us: in the latter case, the set of “generators” Y could be chosen to be finite and even not too large (at most n elements in the case of a linear subspace and at most $n+1$ element in the case of an affine subspace in \mathbf{R}^n). In the convex case, a finite set of “generators” not always is enough.

“Good” – closed – convex sets in \mathbf{R}^n admit also “outer” description, specifically, a closed convex set in \mathbf{R}^n always is a solution set of a system $a_i^T x \leq b_i$, $i = 1, 2, \dots$ of *countably many* nonstrict linear inequalities. Here again, the result is instructive, but incomparably less useful than its linear/affine subspace counterparts, since our abilities to handle infinite (even countable) systems of linear inequalities are severely restricted.

2.1.4 Cones

Cones: definition. An important for us particular type of convex sets is formed by *cones*. By definition, a cone is a nonempty convex set X comprised of rays emanating from the origin, that is, such that $tx \in X$ whenever $x \in X$ and $t \geq 0$. An immediate observation (check it!) is that X is a cone if and only if X is nonempty and is closed w.r.t. taking conic combinations (linear combinations with nonnegative coefficients) of its elements.

Examples. Important for us will be *polyhedral cones* which, by definition, are the solution sets of finite systems of *homogeneous* linear inequalities:

$$X \text{ is a polyhedral cone} \Leftrightarrow \exists A : X = \{x \in \mathbf{R}^n : Ax \leq 0\}.$$

In particular, the *nonnegative orthant* $\mathbf{R}_+^n = \{x \in \mathbf{R}^n : x \geq 0\}$ is a polyhedral cone.

“Calculus” of cones in its most important (and most elementary) part is as follows (check the validity of the claims!):

1. *Taking intersection:* if X_1, X_2 are cones in \mathbf{R}^n , so is their intersection $X_1 \cap X_2$. In fact, the intersection $\bigcap_{\alpha \in \mathcal{A}} X_\alpha$ of a whatever family $\{X_\alpha\}_{\alpha \in \mathcal{A}}$ of cones in \mathbf{R}^n is a cone;
2. *Taking arithmetic sum:* if X_1, X_2 are cones in \mathbf{R}^n , so is the set $X_1 + X_2 = \{x = x_1 + x_2 : x_1 \in X_1, x_2 \in X_2\}$;
3. *Taking linear image:* if X is a cone in \mathbf{R}^n and A is an $m \times n$ matrix, then the set $AX := \{Ax : x \in X\} \subset \mathbf{R}^m$ – the image of X under the linear mapping $x \mapsto Ax : \mathbf{R}^n \rightarrow \mathbf{R}^m$ – is a cone in \mathbf{R}^m ;
4. *Taking inverse linear image:* if X is a cone in \mathbf{R}^n and A is an $n \times k$ matrix, then the set $\{y \in \mathbf{R}^k : Ay \in X\}$ – the inverse image of X under the linear mapping $y \mapsto Ay : \mathbf{R}^k \rightarrow \mathbf{R}^n$ – is a cone in \mathbf{R}^k ;
5. *Taking direct products:* if $X_i \subset \mathbf{R}^{n_i}$ are cones, $1 \leq i \leq k$, so is the direct product $X_1 \times \dots \times X_k \subset \mathbf{R}^{n_1 + \dots + n_k}$;
6. *Passing to the dual cone:* if X is a cone in \mathbf{R}^n , so is its *dual cone* defined as

$$X_* = \{y \in \mathbf{R}^n : y^T x \geq 0 \ \forall x \in X\}.$$

Conic hulls. Similarly to what we observed above, given a nonempty set $X \subset \mathbf{R}^n$ and taking all conic combinations of vectors from X , we get a cone (called the *conic hull* of X , notation: $\text{Cone}(X)$) which is the smallest, w.r.t. inclusion, among the cones containing X . For example, the nonnegative orthant \mathbf{R}_+^n is the conic hull of the set comprised of all n basic orths in \mathbf{R}^n .

2.2 Preparing Tools

In this section, we develop technical tools to be used later. Our ultimate goal is to prove the following

Theorem [Homogeneous Farkas Lemma] A vector $a \in \mathbf{R}^n$ is a conic combination of vectors $a_1, \dots, a_m \in \mathbf{R}^n$ iff the linear inequality

$$a^T x \geq 0 \quad (2.2.1)$$

is a consequence of the homogeneous system of linear inequalities

$$a_i^T x \geq 0, \quad i = 1, \dots, m. \quad (2.2.2)$$

in variables x , that is, iff every feasible solution x to the system satisfies (2.2.1).

This statement is the key which will unlock basically all the locks to be opened in the sequel.

2.2.1 Caratheodory Theorem

We start with the following statement, highly important by its own right:

Theorem 2.2.1 [Caratheodory Theorem] Let x, x_1, \dots, x_k be vectors from \mathbf{R}^n . If x is a convex combination of vectors x_1, \dots, x_k , then x is a convex combination of at most $n+1$ properly chosen vectors from the collection x_1, \dots, x_k .

Moreover, if the dimension of the set $X = \{x_1, \dots, x_k\}$ is m , then $n+1$ in the above conclusion can be replaced with $m+1$.

Proof. Let us look at all possible representations $x = \sum_{i=1}^k \lambda_i x_i$ of x as a convex combination of vectors x_1, \dots, x_k . We are given that the corresponding family is nonempty; then it definitely contains a minimal in the number of actual terms (i.e., those with $\lambda_i \neq 0$) representation. All we should prove is that the number of actual terms in this minimal representation is $\leq n+1$. We can assume w.l.o.g. that the minimal representation in question is $x = \sum_{i=1}^s \lambda_i x_i$; from minimality, of course, $\lambda_i > 0$, $1 \leq i \leq s$. Assume, on the contrary to what should be proved, that $s > n+1$, and let us lead this assumption to a contradiction. Indeed, when $s > n+1$, the homogeneous system of linear equations

$$\begin{aligned} \sum_{i=1}^s \delta_i x_i &= 0 \quad [n \text{ scalar equations}] \\ \sum_{i=1}^s \delta_i &= 0 \quad [1 \text{ scalar equation}] \end{aligned}$$

in $s > n+1$ variables δ has more variables than equations and thus has a nontrivial (with not all entries equal to zero) solution $\bar{\delta}$. Observe that we have

$$\sum_{i=1}^s \underbrace{[\lambda_i + t\bar{\delta}_i]}_{\lambda_i(t)} x_i = x, \quad \sum_{i=1}^s \lambda_i(t) = 1 \quad (!)$$

for all $t \geq 0$. Now, since $\sum_i \bar{\delta}_i = 0$ and not all $\bar{\delta}_i$ are zeros, among the reals $\bar{\delta}_i$ are strictly negative, meaning that for large enough values of t , not all of the coefficients $\lambda_i(t)$ are nonnegative. At the same time, when $t = 0$, these coefficients are positive. It follows that there exists the largest $t = \bar{t} \geq 0$ such that all $\lambda_i(t)$ are still positive; and since for a larger value of t not all $\lambda_i(t)$ are positive, the nonnegative reals $\lambda_i(\bar{t})$, $i = 1, \dots, s$, include one or more zeros.⁵ When $t = \bar{t}$, (!) says that x is a convex combination of x_1, \dots, x_s , the coefficients being $\lambda_i(\bar{t})$; but some of these coefficients are zeros, thus, we managed to represent x as a convex combination of *less than* s of the vectors x_1, \dots, x_k , which contradicts the origin of s . We have arrived at the required contradiction.

⁵In fact we could, of course, skip this explanation and point out \bar{t} explicitly: $\bar{t} = \min_{i: \bar{\delta}_i < 0} [-\lambda_i / \bar{\delta}_i]$.

The second part of the statement is in fact nothing but the first part in a slight disguise. Indeed, let $M = a + L$ be the affine span of x_1, \dots, x_k ; then clearly $x \in M$. Shifting all vectors x_1, \dots, x_k, x by $-a$ (which affects neither the premise, nor the conclusion of the statement we want to prove), we can assume that the affine span of x_1, \dots, x_k is the linear subspace L of dimension $m = \dim \{x_1, \dots, x_k\}$ to which M is parallel. Note that $x \in L$ along with x_1, \dots, x_k , and we lose nothing when thinking about all vectors x, x_1, \dots, x_k as of vectors in \mathbf{R}^m (since as far as linear operations are concerned – and these are the *only* operations underlying our assumptions and targets) L is nothing but \mathbf{R}^m . Invoking the already proved part of the statement, we arrive at its remaining part.⁶ \square

Remark 2.2.1 Note that the result stated in Caratheodory Theorem is sharp: without additional assumptions on x_1, \dots, x_k , you cannot replace $n + 1$ and $m + 1$ with smaller numbers. E.g., given $m \leq n$, consider collection of $m + 1$ vectors in \mathbf{R}^n as follows: $x_0 = 0, x_1 = e_1, \dots, x_m = e_m$, where e_1, \dots, e_n are the basic orths (see p. 51). These vectors clearly are affine independent (why?), so that $\dim \{x_0, x_1, \dots, x_m\} = m$, and the vector $x = \frac{1}{m+1}[x_0 + \dots + x_m]$ – which is a convex combination of x_0, \dots, x_m – admits exactly one representation as an affine (and thus – as a convex) combination of x_0, \dots, x_m (Theorem 2.1.2). Thus, in any representation of x as a convex combination of x_0, x_1, \dots, x_m all these $m + 1$ vectors should be present with positive coefficients.

Illustration. Let us look at the following story:

In the nature, there are 26 “pure” types of tea, denoted A, B, ..., Z; all other types are mixtures of these “pure” types. What they sell in the market, are certain blends of tea, not the pure types; there are totally 111 blends which are sold.

John prefers a specific blend of tea which is not sold in the market; from long experience, he found that in order to get the blend he prefers, he can buy 93 of the 111 market blends and mix them in certain proportion.

An OR student (known to be good in this subject) pointed out that in fact John could produce his favorite blend of tea by appropriate mixing of just 27 of the properly selected market blends. Another OR student pointed out that only 26 of market blends are enough, and the third student said that 24 also is enough. John did not believe in neither of these recommendations, since no one of the students asked him what his favorite blend is. Is John right?

The answer is that the first two students definitely are right, while the third can be wrong. Indeed, we can identify a unit (in weight) amount of a blend of tea with $n = 26$ -dimensional vector $x = [x_A; x_B; \dots; x_Z]$, where entries in x are the weights of the corresponding pure component of the blend; the resulting vector is nonnegative, and the sum of its entries equals to 1 (which is the total weight of our unit of blend). With this identification, let \bar{x} be the blend preferred by John, and let x^1, \dots, x^N be the market blends ($N = 111$). What we know is that John can get a unit amount of his favorite blend by buying market blends in certain amounts $\lambda_i, i = 1, \dots, N$,

⁶We believe the concluding reasoning should be carried out exactly once; in the sequel in similar situations we will just write “We can assume w.l.o.g. that the affine span of x_1, \dots, x_k is the entire \mathbf{R}^n .”

and putting them together, that is, we know that

$$\bar{x} = \sum_{i=1}^N \lambda_i x^i. \quad (*)$$

Of course, λ_i are nonnegative due to their origin; comparing “weights” (sums of entries) of the right- and the left hand side in the vector equality (*), we see that $\sum_i \lambda_i = 1$. Thus, the story tells us that the 26-dimensional vector \bar{x} is a convex combination of N vectors x^1, \dots, x^N . By the first part of the Caratheodory Theorem, x can be represented as a convex combination of $26 + 1 = 27$ properly chosen vectors x^i , which justifies the conclusion of the first student. Noting that in fact x^1, \dots, x^N, \bar{x} belong to the hyperplane $\{x : x_A + x_B + \dots + x_Z = 1\}$ in \mathbf{R}^{26} , we conclude that the dimension of $\{x^1, \dots, x^N\}$ is at most the dimension of this hyperplane, which is $m = 25$. Thus, the second part of Caratheodory Theorem says that just $m + 1 = 26$ properly chosen market blends will do, so that the second student is right as well. As about the third student, whether he is right or not, it depends on what are the vectors \bar{x}, x^1, \dots, x^N . E.g., it may happen that $\bar{x} = x^1$ and John merely missed this fact – then the third student is right. On the other hand, it may happen that x^1, \dots, x^N are just the 26 “pure” teas (basic orths), some of them repeated (who told us that the same blend cannot be sold under several different names?). If every basic orth is present in the collection x^1, \dots, x^N and the favorite blend of John is $\bar{x} = [1/26; \dots; 1/26]$, it indeed can be obtained as mixture of market blends, but such a mixture should contain at least 26 of these blends. Note that the third student would definitely be right if the dimension of $\{x^1, \dots, x^N\}$ were < 24 (why?).

2.2.2 Radon Theorem

Theorem 2.2.2 [Radon Theorem] *Let x_1, \dots, x_k be a collection of $k > n + 1$ vectors from \mathbf{R}^n . Then one can split the index set $I = \{1, \dots, k\}$ into two nonempty and non-overlapping subsets I_1 and I_2 such that the convex hulls of the sets $\{x_i : i \in I_1\}$ and $\{x_i : i \in I_2\}$ intersect.*

Proof follows the same idea as for Caratheodory Theorem. Specifically, consider the homogeneous system of linear equations in variables $\delta_1, \dots, \delta_k$:

$$\begin{aligned} \sum_{i=1}^k \delta_i x_i &= 0 \text{ [} n \text{ scalar equations]} \\ \sum_{i=1}^k \delta_i &= 0 \text{ [1 scalar equation]} \end{aligned}$$

Since $k \geq n + 2$, the number of equations in this system is less than the number of variables; and since the system is homogeneous, it therefore has a nontrivial solution $\bar{\delta}$. Now let $I_1 = \{i : \delta_i > 0\}$ and $I_2 = \{i : \delta_i \leq 0\}$. The sets I_1 and I_2 clearly form a partition of I , and both of them are nonempty; indeed, since $\sum_i \bar{\delta}_i = 0$ and not all $\bar{\delta}_i$ are zeros, there definitely are strictly positive and strictly negative among $\bar{\delta}_i$.

Now let us set $S = \sum_{i \in I_1} \bar{\delta}_i$. The equations from our system read

$$\begin{aligned} \sum_{i \in I_1} \bar{\delta}_i x_i &= \sum_{i \in I_2} [-\bar{\delta}_i] x_i \\ \sum_{i \in I_1} \bar{\delta}_i &= S = \sum_{i \in I_2} [-\bar{\delta}_i] \end{aligned}$$

Setting $\lambda_i = \bar{\delta}_i / S$, $i \in I_1$, $\mu_i = -\bar{\delta}_i / S$, $i \in I_2$, we get $\lambda_i \geq 0$, $\mu_i \geq 0$, and the above reads

$$\begin{aligned} \sum_{i \in I_1} \lambda_i x_i &= \sum_{i \in I_2} \mu_i x_i \\ \sum_{i \in I_1} \lambda_i &= 1 = \sum_{i \in I_2} \mu_i \end{aligned}$$

meaning that $\text{Conv}\{x_i : i \in I_1\} \cap \text{Conv}\{x_i : i \in I_2\} \neq \emptyset$. □

2.2.3 Helley Theorem

Theorem 2.2.3 [Helley Theorem] *Let A_1, \dots, A_N be nonempty convex sets in \mathbf{R}^n .*

(i) *If every $n + 1$ of the sets A_i have a point in common, then all N sets A_i have a point in common.*

(ii) *If the dimension of $A_1 \cup \dots \cup A_N$ is m and every $m + 1$ of the sets A_i have a point in common, then all N sets A_i have a point in common.*

Proof. By exactly the same reasons as in the proof of Caratheodory Theorem, (ii) is a straightforward consequence of (i) (replace the “universe” \mathbf{R}^n with $\text{Aff}\{\bigcup_i A_i\}$), so that all we need is to prove (i). This will be done by induction in the number N of the sets. There is nothing to prove when $N \leq n + 1$; thus, all we need is to verify that the statement is true for a family of $N > n + 1$ convex sets A_i , given that the statement is true for every family of $< N$ convex sets (this is our inductive hypothesis). This is easy: let us form the N sets

$$B_1 = A_2 \cap A_3 \cap \dots \cap A_N, B_2 = A_1 \cap A_3 \cap \dots \cap A_N, \dots, B_N = A_1 \cap A_2 \cap \dots \cap A_{N-1}$$

That is, B_i is the intersection of $N - 1$ sets $A_1, \dots, A_{i-1}, A_{i+1}, \dots, A_N$. By inductive hypothesis, these sets are nonempty (and are convex along with A_1, \dots, A_N). Let us choose in the (nonempty!) set B_i a point x_i , $i = 1, \dots, N$, thus ending up with a collection x_1, \dots, x_N of $N > n + 1$ points from \mathbf{R}^n . Applying Radon Theorem, we can split this collection into two parts with intersecting convex hulls; to save notation – and of course w.l.o.g. – we can assume that this partition is $I_1 = \{1, \dots, m\}$, $I_2 = \{m + 1, \dots, N\}$, so that

$$\exists b \in \text{Conv}\{x_1, \dots, x_m\} \cap \text{Conv}\{x_{m+1}, \dots, x_N\}.$$

We claim that $b \in A_i$ for all i , so that the intersection of all A_i is nonempty; this would complete the inductive step and thus the proof of Helley Theorem. To justify our claim, note that when $i \leq m$, the point x_i belongs to B_i and thus to every one of the sets A_{m+1}, \dots, A_N (by construction of B_i). Thus, every one of the points x_1, \dots, x_m belongs to every set A_i with $i > m$; but then the latter set, being convex, contains $b \in \text{Conv}\{x_1, \dots, x_m\}$. The bottom line is that $b \in A_i$ whenever $i > m$. By “symmetric” reasoning, $b \in A_i$ whenever $i \leq m$. Indeed, whenever $i > m$, the point x_i belongs to B_i and thus to every one of the sets A_1, \dots, A_m (by construction of B_i). Thus, every one of the points x_{m+1}, \dots, x_N belongs to every set A_i with $i \leq m$; being convex, the latter set contains also the point $b \in \text{Conv}\{x_{m+1}, \dots, x_N\}$, as claimed. \square

Remark 2.2.2 Note that the Helley Theorem is “as sharp as it could be:” we can easily point out $n + 1$ nonempty convex sets A_1, \dots, A_{n+1} in \mathbf{R}^n such that every n of them have a point in common, while the intersection of all $n + 1$ sets is empty. An example is given by $A_i = \{x \in \mathbf{R}^n : x_i \leq 0\}$, $i = 1, \dots, n$, $A_{n+1} = \{x \in \mathbf{R}^n : \sum_i x_i \geq 1\}$.

Illustration 1: Let S be a set comprised of 1,000,000 distinct points on the axis and $f(s)$ be a real-valued function on this set. Assume that for every 7-point subset S' of S there exists an algebraic polynomial $p(s)$ of degree ≤ 5 such that $|p(s) - f(s)| \leq 0.01$ whenever $s \in S'$. We now want to find a spline of degree ≤ 5 (a piecewise polynomial function on the axis with pieces – algebraic polynomials of degree ≤ 5) which approximates f at every point of S within accuracy 0.01. How many pieces should we take?

The answer is: just one. Indeed, we can identify a polynomial $p(s) = p_1 + p_1s + \dots + p_5s^5$ of degree ≤ 5 with its vector of coefficients $[p_0; \dots; p_5] \in \mathbf{R}^6$. For a fixed $s \in S$, the set of (vectors of coefficients) of polynomials which approximate $f(s)$ within accuracy 0.01 is $P_s = \{[p_0; \dots; p_5] : |f(s) - p_0 - p_1s - \dots - p_5s^5| \leq 0.01\}$; we see that the set is polyhedral and thus is convex. What is given to us is that every 7 sets from the 1,000,000-set family $\{P_s : s \in S\}$ have a point in common. By Helley Theorem, all 1,000,000 sets have a point p_* in common, and the corresponding polynomial of degree ≤ 5 approximates f at every point from S within accuracy 0.01.

Illustration 2: The daily functioning of a plant is described by the system of linear constraints

$$\begin{aligned} (a) \quad Ax &\leq f \in \mathbf{R}^{10} \\ (b) \quad Bx &\geq d \in \mathbf{R}^{2009} \\ (c) \quad Cx &\leq c \in \mathbf{R}^{2000} \end{aligned} \tag{!}$$

Here

- x is the decision vector – production plan for the day;
- f is *nonnegative* vector of resources (money, manpower, electric power, etc.) available for the day;
- d is the vector of daily demands on different kinds on plant's production.

The plant works as follows. In the evening of day $t - 1$, the manager should order the resources f for the next day; when doing so, he does not know exactly what will be the vector of demands for the next day, but has a collection $D = \{d^1, \dots, d^{1,000,000}\}$ of 1,000,000 demand scenarios and knows that the actual demand of day t will be a point from this set. The goal of the manager is to order the resources f in the evening of day $t - 1$ in such a way that when in the next morning the actual vector of demands of day t will become known, it will be possible to find a production plan x which satisfies the constraints (!).

Finally, the manager knows that every scenario demand $d^i \in D$ can be “served,” in the aforementioned sense, by properly chosen vector $f^i = [f_1^i; \dots; f_{10}^i] \geq 0$ of resources at the cost $\sum_{j=1}^{10} c_j f_j^i$ not exceeding \$1 ($c_j \geq 0$ are given prices of the resources). How much money should a smart manager spend on the next-day resources in order to guarantee that the tomorrow demand will be satisfied?

The answer is: \$ 11 is enough. Indeed, let F_i be the set of all resource vectors $f \geq 0$ which allow to satisfy demand $d^i \in D$. This set is convex (check it!), and we know that it contains a vector f^i which costs at most \$ 1. Now let A_i be the set of all nonnegative resource vectors f which cost at most \$ 11 and allow to satisfy the demand d^i . This set also is convex (as the intersection of the convex set F_i and the polyhedral - and thus convex - set $\{f : f \geq 0, c^T f \leq 11\}$). We claim that every 11 of the convex sets $A_i \subset \mathbf{R}^{10}$ have a point in common. Indeed, given these 11 sets $A_{i_1}, \dots, A_{i_{11}}$, consider the vector of resources $f = f^{i_1} + \dots + f^{i_{11}}$. Since f^{i_p} allows to satisfy the demand d^{i_p} and $f \geq f^{i_p}$, f allows to satisfy the same demand as well (look at (!)); since every f^{i_p} costs at most \$1, f costs at most \$ 11. Thus, $f \geq 0$ allows to satisfy demand d^{i_p} and costs at most \$ 11 and this belongs to A_{i_p} , $1 \leq p \leq 11$. By Helley Theorem, all A_i have a point in common, let it be denoted f_* . By its origin, this is a nonnegative vector with cost ≤ 11 , and since it belongs to every A_i , it allows to satisfy every demands $d^i \in D$.

2.2.4 Homogeneous Farkas Lemma

Consider the situation as follows: we are given a finite system of homogeneous linear inequalities

$$a_i^T x \geq 0 \quad i = 1, \dots, m \quad (2.2.3)$$

in variables $x \in \mathbf{R}^n$, along with another homogeneous linear inequality

$$a^T x \geq 0 \quad (2.2.4)$$

which we will call the *target* one. The question we are interested is: *when (2.2.4) is a consequence of the system (2.2.3), meaning that whenever x satisfies the system, it satisfies the target inequality as well?*

There is a trivial *sufficient* condition for the target inequality to be a consequence of the system, specifically, the representability of the target inequality as a weighted sum, with non-negative coefficients, of the inequalities form the system. Specifically, we have the following observation:

Observation 2.2.1 *If a is a conic combination of a_1, \dots, a_m :*

$$\exists \lambda_i \geq 0 : a = \sum_{i=1}^m \lambda_i a_i, \quad (2.2.5)$$

then the target inequality (2.2.4) is a consequence of the system (2.2.3).

Indeed, let λ_i be as in (2.2.5), and let x be a solution of (2.2.3). Multiplying the inequalities $a_i^T x \geq 0$ by the nonnegative weights λ_i and summing up, we get $a^T x \equiv [\sum_i \lambda_i a_i]^T x = \sum_i \lambda_i a_i^T x \geq 0$. \square

The Homogeneous Farkas Lemma is an incomparably deeper result with states that the above trivial sufficient condition is in fact *necessary* for the target inequality to be a consequence of the system.

Theorem 2.2.4 [Homogeneous Farkas Lemma] *The target inequality (2.2.4) is a consequence of the system (2.2.3) iff a is a conic combination of a_1, \dots, a_m .*

Equivalent, and sometimes more instructive, form of this statement reads:

It is easy to certify both that a is a conic combination of a_1, \dots, a_m , and that a is not a conic combination of a_1, \dots, a_m :

— *to certify the first fact, it suffices to point out nonnegative λ_i such that $a = \sum_i \lambda_i a_i$;*

— *to certify the second fact, it suffices to point out x such that $a_i^T x \geq 0, i = 1, \dots, m$, and $a^T x < 0$.*

a is a conic combination of a_1, \dots, a_m iff the certificate of the first kind exists, and a is not a conic combination of a_1, \dots, a_m iff the certificate of the second kind exists.

Proof of HFL. We have already seen that *if a is a conic combination of a_1, \dots, a_m , then the target inequality is a consequence of the system.* All we need is to prove the inverse statement:

(#) *if the target inequality is a consequence of the system, then a is a conic combination of a_1, \dots, a_m .*

Intelligent proof of (#). Observe that the set $X = \{x = \sum_{i=1}^m \lambda_i a_i : \lambda_i \geq 0\}$ is polyhedrally representable: $K = \{x : \exists \lambda : x = \sum_i \lambda_i a_i, \lambda \geq 0\}$ and as such is polyhedral (Fourier-Motzkin elimination, Theorem 1.2.1):

$$X = \{x \in \mathbf{R}^n : d_\ell^T x \geq \delta_\ell, \ell = 1, \dots, L\} \quad (*)$$

for some d_ℓ, δ_ℓ ; observe that $\delta_\ell \leq 0$ due to the evident inclusion $0 \in X$. Now let the target inequality $a^T x \geq 0$ be a consequence of the system $a_i^T x \geq 0, 1 \leq i \leq m$, and let us lead to contradiction the assumption that a is not a conic combination of a_i , or, which is the same, the assumption that $a \notin X$. Assuming $a \notin X$ and looking at (*), there exists ℓ_* such that $d_{\ell_*}^T a < \delta_{\ell_*}$, and thus $d_{\ell_*}^T a < 0$ due to $\delta_{\ell_*} \leq 0$. On the other hand, we have $\lambda a_i \in X$ for all $\lambda \geq 0$ and all i , meaning that $\lambda d_{\ell_*}^T a_i \geq \delta_{\ell_*}$ for all $\lambda \geq 0$ and all i , whence $d_{\ell_*}^T a_i \geq 0$ for all i (look what happens when $\lambda \rightarrow +\infty$). Thus, d_{ℓ_*} satisfies the system $a_i^T x \geq 0, 1 \leq i \leq m$, and violates the target inequality $a^T x \geq 0$, which under the premise of (#) is impossible; we have arrived at a desired contradiction. \square

Alternative proof of (#) based on Helley Theorem. There is nothing to prove when $a = 0$, since then a indeed is a conic combination of a_1, \dots, a_m . Thus, from now on we assume that $a \neq 0$ and that (2.2.4) is a consequence of (2.2.3); our goal is to derive from these assumptions that a is a conic combination of a_1, \dots, a_m .

1⁰. Let us set $A_i = \{x \in \mathbf{R}^n : a_i^T x \geq 0, a^T x = -1\}$. Note that every A_i is a polyhedral set and as such is convex (perhaps, empty) and that the intersection of all m sets A_1, \dots, A_m definitely is empty (indeed, a vector x from this intersection, if exists, solves the system and does not solve the target inequality, which is impossible). Let us extract from the family of sets A_1, \dots, A_m with empty intersection a minimal, w.r.t. inclusion, subfamily with the same property. W.l.o.g. we can assume that this subfamily is A_1, \dots, A_k . Thus, $k \geq 1$, the intersection of A_1, \dots, A_k is empty, and either $k = 1$ (meaning that A_1 is empty), or the intersection of every $k - 1$ sets from A_1, \dots, A_k is nonempty.

2⁰ We claim that $a \in L := \text{Lin}\{a_1, \dots, a_k\}$. Indeed, otherwise a has a nonzero projection h onto L^\perp , so that $h^T a_i = 0, i = 1, \dots, k$, and $h^T a = h^T h > 0$. Setting $x = -\frac{1}{h^T h} h$, we get $a_i^T x = 0, 1 \leq i \leq k$, and $a^T x = -1$; thus, h belongs to A_1, \dots, A_k , and these sets have a point in common, which in fact is not the case.

3⁰. We claim – and this is the central component of the proof – that a_1, \dots, a_k are linearly independent, or, which is the same, that $\dim L = k$. Since L is linearly spanned by a_1, \dots, a_k , the only alternative to $\dim L = k$ is $\dim L < k$; we assume that the latter is the case, and let us lead this assumption to a contradiction. Observe, first, that $k > 1$, since otherwise $L = \{0\}$ due to $\dim L < k$, implying that $a = 0$ (we already know that $a \in L$), which is not the case. Further, consider the hyperplane $\Pi = \{x \in L : a^T x = -1\}$ in L . Since $0 \neq a \in L$, Π indeed is a hyperplane, and thus $\dim P = \dim L - 1 < k - 1$. Now, the orthogonal projections B_i of the sets $A_i = \{x : a_i^T x \geq 0, a^T x = -1\}$ onto $L, 1 \leq i \leq k$, clearly belong to Π and to A_i (since when projecting orthogonally $x \in A_i$ onto L the inner products with a and a_i remain intact due to $a \in L, a_i \in L$). $B_i, i = 1, \dots, k \geq 1$, are convex subsets of Π , and the intersection of every $k - 1 > 0$ of the sets B_i is nonempty (indeed, it contains the projection onto L of every point from the intersection of the corresponding A_i , and this intersection is nonempty). Since $\dim P + 1 < k$, we conclude that the intersection of every $P + 1$ of the sets B_1, \dots, B_k is nonempty, whence the intersection of all k of the sets b_1, \dots, b_k is nonempty (Helley Theorem).

Recalling that $B_i \subset A_i$, we conclude that the intersection of A_1, \dots, A_k is nonempty, which is a desired contradiction (recall how k and A_1, \dots, A_k were chosen).

4⁰. Now it is easy to complete the proof. By 2⁰, $a \in L = \text{Lin}\{a_1, \dots, a_k\}$, that is, $a = \sum_{i=1}^k \lambda_i a_i$ with certain λ_i ; we are about to prove that all λ_i here are nonnegative, which will bring us to our goal – to prove that a is a conic combination of a_1, \dots, a_m . In order to verify that $\lambda_i \geq 0$, $1 \leq i \leq k$, assume, on the contrary, that not all λ_i are nonnegative, say, that $\lambda_1 < 0$. Since a_1, \dots, a_k are linearly independent by 3⁰, by Linear Algebra there exists a vector $\bar{x} \in \mathbf{R}^n$ such that $a_1^T \bar{x} = 1/|\lambda_1|$, $a_2^T \bar{x} = 0, \dots, a_k^T \bar{x} = 0$. We have $a^T \bar{x} = \sum_i \lambda_i a_i^T \bar{x} = \lambda_1/|\lambda_1| = -1$, while, by construction, $a_i^T \bar{x} \geq 0$, $i = 1, \dots, k$. We see that $\bar{x} \in A_1 \cap \dots \cap A_k$, which is impossible, since the right hand side intersection is empty. Thus, assuming that not all of $\lambda_1, \dots, \lambda_k$ are nonnegative, we arrive at a contradiction. \square

The HFL is the key instrument in our further developments. As for now, here is one of fundamental results readily given by HFL (in fact, this result is an equivalent reformulation of HFL):

Theorem 2.2.5 *Let $K = \{x \in \mathbf{R}^n : Ax \leq 0\}$ be a polyhedral cone, and K^* be its dual cone:*

$$K^* = \{y \in \mathbf{R}^n : y^T x \geq 0 \forall x \in K\}.$$

Then K^ is the conic hull of the (transposes of the) rows of $-A$:*

$$K^* = \{y = A^T \lambda : \lambda \leq 0\}. \quad (2.2.6)$$

In particular, K is the cone dual to K^ :*

$$K = \{x \in \mathbf{R}^n : x^T y \geq 0 \forall y \in K^*\}.$$

Proof. Let the rows of A be a_1^T, \dots, a_m^T . By definition, vectors $a \in K^*$ are vectors which have nonnegative inner products with all vectors from K , that is, with all vectors which have nonnegative inner products with the vectors $-a_1, \dots, -a_m$. Equivalently: $a \in K^*$ is and only if the linear inequality $a^T x \geq 0$ is a consequence of the system of linear inequalities $-a_i^T x \geq 0$, $i = 1, \dots, m$. By HFL, this is the case if and only if a is a conic combination of $-a_1, \dots, -a_m$, and we arrive at (2.2.6). To get the “in particular” part of the statement, note that in view of (2.2.6) we have

$$(K^*)^* = \{x : x^T A^T \lambda \geq 0 \forall \lambda \leq 0\} = \{x : \lambda^T [Ax] \geq 0 \forall \lambda \leq 0\} \underbrace{=}_{(*)} \{x : Ax \leq 0\} = K,$$

where $(*)$ is given by the following evident observation: a vector has nonnegative inner products with all vectors which are ≤ 0 if and only if this vector itself is ≤ 0 . \square

Note that the relation $(K^*)^* = K$ is in fact true for all closed cones, not necessarily polyhedral ones; this is a far-reaching extension of the rule $(L^\perp)^\perp = L$ for linear subspaces L (note that a linear subspace is a very special case of a cone, and the cone dual to a linear subspace L is L^\perp (why?)).

2.3 Faces, Vertices, Recessive Directions, Extreme Rays

In this section, we prepare tools which will allow us to prove Theorem on the Structure of a Polyhedral Set announced at the beginning of lecture. We focus on a polyhedral set

$$X = \{x \in \mathbf{R}^n : Ax \leq b\}, A = \begin{bmatrix} a_1^T \\ \vdots \\ a_m^T \end{bmatrix} \in \mathbf{R}^{m \times n}. \quad (2.3.1)$$

Unless otherwise is explicitly stated, we assume in the sequel that X is nonempty, denote by M the affine span of X :

$$M = \text{Aff}(X),$$

and denote by \mathcal{I} the set of indices of the constraints: $\mathcal{I} = \{1, 2, \dots, m\}$.

2.3.1 Faces

A *face* of the nonempty polyhedral set X given by (2.3.1), by definition, is a *nonempty subset of X comprised of all points where the inequalities $a_i^T x \leq b_i$ with indices from certain subset I of \mathcal{I} are satisfied as equalities* (“are active” in the optimization slang). Thus, a face of X is a *nonempty subset of X which can be represented as*

$$X_I = \left\{ x : \begin{array}{l} a_i^T x = b_i, i \in I \\ a_i^T x \leq b_i, i \in \bar{I} \end{array} \right\}, \quad (2.3.2)$$

where I is a subset of the set $\mathcal{I} = \{1, \dots, m\}$ of indices of the linear inequalities defining X , and \bar{I} is the complement of I in \mathcal{I} . Note that by (2.3.2),

- a face X_I of a nonempty polyhedral set is itself a nonempty polyhedral set, and
- the intersection of two faces X_{I_1}, X_{I_2} of X is the set $X_{I_1 \cup I_2}$, and thus is a face of X , provided that it is nonempty.

Besides this, we have the following:

- A face of a face X_I of a polyhedral set X can be represented as a face of X itself.

Indeed, X_I can be represented as the polyhedral set

$$X_I = \left\{ x \in \mathbf{R}^n : \begin{array}{l} a_i^T x \leq b_i, i \in I \\ -a_i^T x \leq -b_i, i \in I \\ a_i^T x \leq b_i, i \in \bar{I} \end{array} \right\}$$

By definition, a face of the latter polyhedral set is obtained from the above description by replacing some of the inequalities with their equality versions in such a way that the resulting system of inequalities and equalities is feasible. When turning one of the inequalities $a_i^T x \leq b_i$, $i \in I$, or $-a_i^T x \leq -b_i$, $i \in I$, into an equality, we do not change X_I , so that we lose nothing by assuming that the inequalities we are turning into equalities to get a face of X_I are from the group $a_i^T x \leq b_i$, $i \in \bar{I}$; in the latter case, the result is as if we were replacing with equalities some of the inequalities defining X , so that the result, being nonempty, indeed is a face of X .

Warning: For the time being, our definition of a face of a polyhedral set is *not* geometric: a face is defined in terms of a particular description of X by a system of linear inequalities rather than in terms of X itself. This is where “can be represented as a face” instead of “is a face” in the latter statement. In the mean time we shall see that faces can be defined solely in terms of X .

Example. Consider the *standard simplex*

$$\Delta_n = \{x \in \mathbf{R}^n : x_i \geq 0, 1 \leq i \leq n, \sum_i x_i \leq 1\} \quad (2.3.3)$$

$$\left[\begin{array}{l} \text{in the format of (2.3.1): } m = n + 1, a_i = -e_i, \\ b_i = 0 \text{ for } i = 1, \dots, n, a_{m+1} = [1; \dots; 1], b_{m+1} = 1 \end{array} \right]$$

In this case, every subset I of $\mathcal{I} = \{1, \dots, n + 1\}$, *except for \mathcal{I} itself*, defines a face of Δ_n ; such a face is comprised of all points from Δ_n which have prescribed coordinates equal to zero (indices of these coordinates form the intersection of I with $\{1, \dots, n\}$), and perhaps the unit sum of entries (the latter is the case when $n + 1 \in I$).

According to our definition, the entire X is a face of itself (this face corresponds to $I = \emptyset$). All faces which are distinct from X (and thus form proper — distinct from the entire X and from \emptyset — subsets of X) are called *proper*. E.g., all faces of the standard simplex Δ_n ($n > 0$) corresponding to proper ($I \neq \emptyset, I \neq \mathcal{I}$) subset I of \mathcal{I} are proper.

Proposition 2.3.1 *Let X be a nonempty polyhedral set given by (2.3.1). Then every proper face X_I of X has dimension strictly less than the one of X .*

Proof. Let X_I be a proper face of X ; then definitely $I \neq \emptyset$. Let us look at the linear equations $a_i^T x = b_i$, $i \in I$. If every one of these equations is satisfied by all points from $M = \text{Aff}(X)$, then it is satisfied everywhere on X , whence, comparing (2.3.2) and (2.3.1), $X_I = X$, which is impossible, since X_I is a proper face of X . Thus, there exists $i = i_*$ such that the linear equation $a_{i_*}^T x = b_{i_*}$, which is satisfied everywhere on X_I , is violated somewhere on M . Setting $M^+ = \{x \in M : a_{i_*}^T x = b_{i_*}\}$, we get a nonempty set (it contains X_I which is nonempty) and as such is an affine subspace (since it is a nonempty intersection of two affine subspaces M and $\{x : a_{i_*}^T x = b_{i_*}\}$). Since $M^+ \subset M$ by construction and $M^+ \neq M$, we have $\dim M^+ < \dim M$ (see (2.1.5.b)). It remains to note that $X_I \subset M^+$ due to $X_I \subset X \subset M$ and $a_{i_*}^T x = b_{i_*}$ for all $x \in X_I$, whence $\dim X_I \leq \dim M^+ < \dim M$. \square

2.3.2 Vertices

Definition and characterization

The definition of a vertex is as follows:

Definition 2.3.1 *A vertex (another name – an extreme point) of a nonempty polyhedral set X given by (2.3.1) is a point $v \in \mathbf{R}^n$ such that the singleton $\{v\}$ is a face of X .*

This definition refers to the particular *representation* of the set X (since for the time being, the notion of a face of X is defined in terms of the representation (2.3.1) of X rather than in terms of X itself). It is easy, however, to express the notion of a vertex in terms of X . The next proposition presents both algebraic and geometric characterizations of vertices.

Proposition 2.3.2 *Let $X \subset \mathbf{R}^n$ be a nonempty polyhedral set given by (2.3.1).*

(i) [algebraic characterization of vertices] *A singleton $\{v\}$ is a face of X if and only if v satisfies all inequalities $a_i^T x \leq b_i$ defining X and among those inequalities which are active (i.e., satisfied as equalities) at v there are n with linearly independent a_i .*

(ii) [geometric characterization of vertices] *A point v is a vertex of X iff $v \in X$ and from $v \pm h \in X$ it follows that $h = 0$ (geometrically: v belongs to X and is not the midpoint of a nontrivial – not reducing to a point – segment belonging to X).*

Proof. (i): Let v be a vertex of X . By definition, this means that for a properly chosen $I \subset \mathcal{I}$, a is the unique solution of the system of equality and inequality constraints in variables x :

$$a_i^T x = b_i, i \in I, \quad a_i^T x \leq b_i, i \in \bar{I} \quad (*)$$

W.l.o.g. we may assume that all inequalities $a_i^T x \leq b_i, i \in \bar{I}$, are satisfied at v strictly (indeed, otherwise we could move all indices $i \in \bar{I}$ with $a_i^T v = b_i$ into I ; this transformation of the partition $\mathcal{I} = I \cup \bar{I}$ keeps v a solution of the transformed system $(*)$ and can only decrease the number of solutions to the system; thus, v is the unique solution to the transformed system). Given that all the inequality constraints in $(*)$ are satisfied at v strictly, all we should verify is that among the vectors $a_i, i \in I$, there are n linearly independent. Assuming that it is not the case, there exists a nonzero vector f which is orthogonal to all vectors $a_i, i \in I$. Setting $v_t = v + th$, observe that for all small enough in modulus values of t v_t solves $(*)$. Indeed, the constraints in $(*)$ are satisfied when $t = 0$, whence the equality constraints $a_i^T v_t = b_i, i \in I$, are satisfied for all t due to $a_i^T h = 0, i \in I$. The inequality constraints $a_i^T v_t \leq b_i, i \in \bar{I}$, are satisfied *strictly* when $t = 0$, and therefore every one of them remains valid in an appropriate neighborhood of $t = 0$; since the number of constraints is finite, there exists a single neighborhood which “serves” in this sense all the constraints with $i \in \bar{I}$. The bottom line is that indeed v_t solves $(*)$ for all t ’s close enough to 0; since $h \neq 0$, we see that the solution to $(*)$ is not unique, this arriving at the desired contradiction.

We have proved that *if* v is a vertex of X , *then* the characterization from (i) holds true. To prove the inverse, assume that $v \in X$ and that among the inequalities $a_i^T x \leq b_i$ active at v there are n with linearly independent a_i . Denoting by I the set of indices of the active at v inequalities, we have $v \in X_I$ and therefore X_I is nonempty and thus is a face of X . It remains to note that v is the only point in X_I , since every point x in this set must satisfy the system of equations

$$a_i^T x = b_i, i \in I,$$

and the matrix of this system with n variables is of rank n , so that its solution (which does exist – the system is solved by v !) is unique. (i) is proved.

(ii): Proof of (ii) more or less repeats the above reasoning. In one direction: let v be a vertex of X . By (i), among the inequalities $a_i^T v \leq b_i, i \in \mathcal{I}$, n inequalities with linearly independent a_i ’s are equalities, let their indices form a set I . If now h is such that $v \pm h \in X$, then one has $a_i^T [v \pm h] \leq b_i, i \in I$, which combines with $a_i^T v = b_i, i \in I$, to imply that $a_i^T h = 0$ for all $i \in I$. Since among the vectors $a_i, i \in I$, there are n linearly independent (and thus spanning the entire \mathbf{R}^n), the only vectors h orthogonal to all $a_i, i \in I$, is $h = 0$. Thus, *if* v is a vertex, *then* $v \in X$ and $v \pm h \in X$ implies that $h = 0$. To prove the inverse, let $v \in X$ be such that $v \pm h \in X$ implies that $h = 0$, and let us prove that v is a vertex. Indeed, let I be the set of indices of all inequalities $a_i^T x \leq b_i$ which are active at v . Assuming that there are no n linearly independent among the vectors $a_i, i \in I$, we can find a nonzero f which is orthogonal to all $a_i, i \in I$, so that all points $v_t = v + tf$ satisfy the inequalities $a_i^T v_t \leq b_i, i \in I$. And since the inequalities $a_i^T x \leq b_i, i \notin I$, are satisfied at v strictly (due to how we defined I), the points v_t , same as in the proof of (i), satisfy these inequalities for all t small enough in absolute value. The bottom line is that under our assumption that the set of a_i ’s with $i \in I$ does not contain n linearly independent vectors, there exists small positive t and nonzero vector f such that $v \pm tf$ satisfies all inequalities in (2.3.1) and thus belongs to X ; thus, with $h = tf \neq 0$ we have $v \pm h \in X$, which is impossible. We conclude that among a_i ’s with $i \in I$ there are n linearly independent; invoking (i), v is a vertex. \square

Exercise 2.2 What are the vertices of the polyhedral set shown on figure 2.1.a)?

Answer: the vertices of the triangle shown on figure 2.1.b).

Corollary 2.3.1 The set of extreme points of a nonempty polyhedral set is finite.

Indeed, by Proposition 2.3.2, an extreme point should solve a subsystem of the $m \times n$ system of linear equations $Ax = b$ comprised of n linearly independent equations; the solution to such a subsystem is unique, and the number of subsystems is finite. \square

Exercise 2.3 Prove the following claim:

Let v be a vertex of a polyhedral set X , and $v = \sum_{i=1}^k \lambda_i x_i$ be a representation of v as a convex combination of points $x_i \in X$ where all the coefficients are strictly positive. Then $x_i = v$ for all i . As a corollary, whenever $\text{Conv}(Y) \subset X$ and $v \in \text{Conv}(Y)$, we have $v \in Y$.

Exercise 2.4 Prove that whenever $X_1 \subset X_2$ are polyhedral sets, every extreme point of X_2 which belongs to X_1 is an extreme point of X_1 .

We add to the above results the following simple and important

Proposition 2.3.3 A vertex of a face of a nonempty polyhedral set X is a vertex of X itself.

Proof. We have seen that a face of a face X_I of a polyhedral set X can be represented as a face of X itself. It follows that a vertex of a face X_I of X (which, by definition, is a singleton face of X_I) can be represented as a singleton face of X and thus is a vertex of X .

Discussion. The crucial role played by vertices of polyhedral sets stems from the facts (which we shall prove in the mean time) that

A. Every bounded nonempty polyhedral set X is the convex hull of the (finite, by Corollary 2.3.1) set of its extreme points; moreover, whenever X is represented as $X = \text{Conv}(Y)$, Y contains the set of extreme points of X .

We shall see also that extreme points form a basic “building block” in the description of an arbitrary nonempty polyhedral set not containing lines, not necessarily a bounded one.

Note that the notion of an extreme point can be extended to the case of convex sets: an extreme point of a convex set Q is a point v of Q which cannot be represented as a midpoint of a nontrivial segment belonging to Q : $v \in Q$ and $v \pm h \in Q$ implies that $h = 0$. The “convex analogy” of **A** is the Krein-Milman Theorem: Every nonempty, bounded and closed convex set Q in \mathbf{R}^n is the convex hull of the set of its extreme points (which now can be infinite); moreover, whenever $Q = \text{Conv}(Y)$, Y contains all extreme points of Q .

B. If the feasible set of a solvable LO program (which always is a polyhedral set) does not contain lines, then among the optimal solutions there are those which are vertices of the feasible set;

C. Vertices of polyhedral set, their algebraic characterization as given by Proposition 2.3.2, and Corollary 2.3.1 are instrumental for simplex-type algorithms of LO.

From the outlined (and many other similar) facts it should be clear that understanding the structure of extreme points of a polyhedral set contributes a lot to understanding of this set and to our abilities to work with it. As an instructive exercise, let us describe the extreme points of two important families of polyhedral sets.

Example: Extreme points of the intersection of $\|\cdot\|_\infty$ - and $\|\cdot\|_1$ balls

Consider the polyhedral set

$$X = \left\{ x \in \mathbf{R}^n : -1 \leq x_i \leq 1, 1 \leq i \leq n, \sum_i |x_i| \leq k \right\}, \quad (2.3.4)$$

where k is a nonnegative integer $\leq n$.

Note: (2.3.4) is *not* a representation of X by a finite set of linear inequalities, since the inequality $\sum_i |x_i| \leq k$ is not linear. To get a polyhedral description of X , we should replace this nonlinear inequality with the system of 2^n linear inequalities $\sum_i \epsilon_i x_i \leq k$ corresponding to all collections of ± 1 coefficients ϵ_i . We, however, have seen that a vertex of a polyhedral set is a geometric notion – a notion which can be expressed solely in terms of the set X , without referring to its polyhedral description.

Note also that geometrically, X is the intersection of the unit box $B_\infty(1) = \{x \in \mathbf{R}^n : -1 \leq x_i \leq 1 \forall i\}$ and the ℓ_1 -ball of radius k $B_1(k) = \{x \in \mathbf{R}^n : \sum_{i=1}^k |x_i| \leq k\}$.

We claim that *the extreme points of X are nothing but the vectors from \mathbf{R}^n with exactly k nonzero coordinates, equal each either to 1, or to -1* . Indeed,

(a) let v be a vector of the outlined type, and let us prove that it is an extreme point of X . By Proposition 2.3.2.(ii) we should prove that if h is such that $v \pm h \in X$, then $h = 0$. Indeed, let $v \pm h \in X$ and let I be the set of indices of the k nonzero coordinates of v . When $i \in I$, then either $v_i = 1$ – and then $v \pm h \in X$ implies that $1 \geq v_i \pm h_i = 1 \pm h_i$, that is, $h_i = 0$, or $v_i = -1$, and then $v \pm h \in X$ implies that $-1 \leq v_i \pm h_i = -1 \pm h_i$, and we again arrive at $h_i = 0$. With this in mind, $v + h \in X$ implies that $k + \sum_{i \notin I} |h_i| = \sum_{i \in I} |v_i| + \sum_{i \notin I} |h_i| \leq k$, whence $h_i = 0$ when $i \notin I$, meaning that $h = 0$, as required.

(b) let v be an extreme point of X , and let us prove that v has exactly k nonzero coordinates, equal to ± 1 . Indeed, let J be the set of indices i for which v_i is neither 1, nor -1 . Observe that J cannot have less than $n - k$ indices, since otherwise v has $> k$ coordinates of magnitude 1 and thus does not belong to X (due to the constraint $\sum_i |x_i| \leq k$ participating in the definition of X). When J contains exactly $n - k$ indices, the same constraint says that $v_i = 0$ when $i \in J$, and then v has exactly k nonzero entries, equal to ± 1 , which is what we claimed. It remains to verify that J cannot contain more than $n - k$ indices. Assuming that this is the case: $\text{Card } J > n - k$, note that then v has at least one entry which is neither -1 , nor 1 (since $n - k \geq 0$); w.l.o.g. we can assume that this entry is v_1 . Since $v \in X$, this entry should belong to $(-1, 1)$. Now, it may happen that $\sum_i |v_i| < k$. In this case the vectors $[v_1 - \delta; v_2; \dots; v_n]$ and $[v_1 + \delta; v_2; \dots; v_n]$ with small enough positive δ belong to X , and thus v is the midpoint of a nontrivial segment belonging to X , which is impossible. Thus, $\sum_i |v_i| = k$. Since the number of entries of magnitude 1 in v is $\ell = n - \text{Card}(J) < k$, we have $\sum_{i \in J} |v_i| = k - \sum_{i \notin J} |v_i| = k - \ell \geq 1$, and since $|v_i| < 1$ for $i \in J$, the relation $\sum_{i \in J} |v_i| \geq 1$ implies that *at least two of the entries v_i , $i \in J$, are nonzero* (and are of magnitude < 1 , as all entries v_i of v with indices from J). W.l.o.g. we can assume that the two entries in question are v_1 and v_2 : $v_1 \neq 0$, $v_2 \neq 0$, $|v_1| < 1$, $|v_2| < 1$. Then the vectors $[v_1 - \text{sign}(v_1)\delta; v_2 + \text{sign}(v_2)\delta; v_3; \dots; v_n]$ and $[v_1 + \text{sign}(v_1)\delta; v_2 - \text{sign}(v_2)\delta; v_3; \dots; v_n]$ for all small positive δ belong to X , and v again is a midpoint of a nontrivial segment belonging to X , which is impossible. \square

Particular cases. When $k = n$, X is nothing but the unit box $\{x \in \mathbf{R}^n : -1 \leq x_i \leq 1, 1 \leq i \leq n\}$, and the above result reads: *the vertices of the unit box are exactly the ± 1 vectors*. Similar

statement for an arbitrary box $\{x \in \mathbf{R}^n : p_i \leq x_i \leq q_i \forall i \leq n\}$ which is nonempty ($p \leq q$) reads: *the vertices of the box are all vectors v with “extreme” coordinates (i.e., $v_i = p_i$ or $v_i = q_i$ for every i) (check it!)*

When $k = 1$, X becomes the unit ℓ_1 -ball $\{x \in \mathbf{R}^n : \sum_i |x_i| \leq 1\}$, and our result reads: *the vertices of the unit ℓ_1 -ball in \mathbf{R}^n are exactly the $2n$ vectors $\pm e_i$, $i = 1, \dots, n$ (as always e_i are the basic orths).*

Modifications. Slightly modifying the above reasoning, one arrives at the useful facts stated in the following

Exercise 2.5 *Verify that whenever k is an integer such that $1 \leq k \leq n$, then*

(i) *The extreme points of the polyhedral set $\{x \in \mathbf{R}^n : 0 \leq x_i \leq 1, 1 \leq i \leq n, \sum_i x_i \leq k\}$ are exactly the Boolean vectors (i.e., vectors with coordinates 0 and 1) with at most k coordinates equal to 1;*

(ii) *The extreme points of the polyhedral set $\{x \in \mathbf{R}^n : 0 \leq x_i \leq 1, 1 \leq i \leq n, \sum_i x_i = k\}$ are exactly the Boolean vectors (i.e., vectors with coordinates 0 and 1) with exactly k coordinates equal to 1.*

Note that the second set is a face of the first one.

Example: Extreme points of the set of double stochastic matrices

An $n \times n$ matrix is called *double stochastic*, if it has nonnegative entries which sum up to 1 in every row and every column. The set of these matrices is the subset

$$\Pi_n = \{x = [x_{ij}] \in \mathbf{R}^{n \times n} = \mathbf{R}^{n^2} : x_{ij} \geq 0 \forall i, j, \sum_i x_{ij} = 1, \sum_j x_{ij} = 1, \forall i, j\};$$

we see that this is a polyhedral set in $\mathbf{R}^{n^2} = \mathbf{R}^{n \times n}$ given by n^2 inequality constraints and $2n$ equality constraints. In fact, we can reduce the number of equality constraints by 1 by dropping one of them, say, $\sum_i x_{i1} = 1$; indeed, if the sum of x_{ij} in every row is 1, then the total sum of entries is n ; and if, in addition, the column sums in all columns except for the first one are equal to 1, then the sum of entries in the first column automatically equals to $n - (n - 1) = 1$.

The following fact has an extremely wide variety of applications:

Theorem 2.3.1 [Birkhoff] *The extreme points of the set of double stochastic $n \times n$ matrices are exactly the $n \times n$ permutation matrices (exactly one nonzero entry, equal to 1, in every row and every column).*

Proof. The fact that permutation matrices are extreme points of the set Π_n of double stochastic matrices is easy: by the above result, these matrices are extreme points of the box $\{[x_{ij}] \in \mathbf{R}^{n \times n} : 0 \leq x_{ij} \leq 1 \forall i, j\}$ which contains Π_n , and it remains to use the statement of Exercise 2.4.

To prove that every vertex v of Π_n is a permutation matrix, let us use induction in n . The base $n = 1$ is evident: Π_1 is a singleton $\{1\}$, and clearly 1 is the only extreme point of this set (see geometric characterization of extreme points, Proposition 2.3.2.(ii)), and this indeed is an 1×1 permutation matrix. Inductive step $n - 1 \Rightarrow n$ is as follows. Let v be an extreme point of Π_n ; as it was already explained, we can think that the latter set is given by n^2 inequalities $x_{ij} \geq 0$ and $2n - 1$ linear equality constraints. Since Π_2 “lives” in \mathbf{R}^{n^2} , algebraic characterization of vertices (Proposition 2.3.2.(i)) says that n^2 linearly independent constraints from the description of Π_n should become active at v . $2n - 1$ linear equality constraints participating in the description

of Π_n contribute $2n - 1$ linearly independent active constraints, and the remaining $n^2 - 2n + 1$ active at v constraints should come from the n^2 constraints $x_{ij} \geq 0$. In other words, *at least* $n^2 - 2n + 1 = (n - 1)^2$ entries in v are zeros. It follows that *there is a column in v with at most one nonzero entry*, since otherwise the number of zero entries in every column were $\leq n - 2$, and the total number of zero entries would be $n(n - 2) < (n - 1)^2$. Now let j_1 be the index of the column where v has at most one nonzero entry. Since the corresponding column sum is 1, this “at most one nonzero entry” means “exactly one nonzero entry, equal to 1.” Since the row sums in v are equal to 1 and the entries are nonnegative, this nonzero entry, equal to 1, is the only nonzero entry in its row, let this row be i_1 . Eliminating from the double stochastic $n \times n$ matrix v the column j_1 and the row i_1 , we get a $(n - 1) \times (n - 1)$ matrix \hat{v} which clearly is double stochastic; since v is a vertex in Π_n , it is completely straightforward to verify (do it!) that \hat{v} is a vertex in Π_{n-1} . By the inductive hypothesis, \hat{v} is an $(n - 1) \times (n - 1)$ permutation matrix; recalling the relation between v and \hat{v} , v is a permutation matrix itself. \square

2.3.3 Recessive Directions

Definition and characterization

Definition 2.3.2 *Let X be a nonempty polyhedral set. A vector $e \in \mathbf{R}^n$ is called a recessive direction of X , if there exists $\bar{x} \in X$ such that the entire ray $\{\bar{x} + te : t \geq 0\}$ emanating from \bar{x} and directed by e belongs to X . The set of all recessive directions of X is called the recessive cone of X , denoted $\text{Rec}(X)$.⁷*

Note that this definition is geometric: it does not refer to a representation of X in the form of (2.3.1).

Examples: • $e = 0$ is a recessive direction of every nonempty polyhedral set.

• Recessive directions of an affine subspace M are exactly the vectors from the parallel linear subspace.

Algebraic characterization of recessive directions. Given a polyhedral description (2.3.1) of a nonempty polyhedral set X , it is easy to characterize its recessive directions:

Proposition 2.3.4 [algebraic characterization of recessive directions] *Let X be a nonempty polyhedral set given by $X = \{x : Ax \leq b\}$, see (2.3.1). Then*

(i) *The recessive directions of X are exactly the vectors from the polyhedral cone*

$$\text{Rec}(X) := \{e : Ae \leq 0\}. \quad (2.3.5)$$

(ii) *One has $X = X + \text{Rec}(X)$, that is, whenever $x \in X$ and $e \in \text{Rec}(X)$, the ray $\{x + te : t \geq 0\}$ is contained in X .⁸*

⁷We shall see in a while that the terminology is consistent – the set of all recessive directions of a polyhedral set X indeed is a cone.

⁸Note the difference between the information provided in (ii) and the definition of a recessive direction e : by the latter, e is a recessive direction if *some* ray directed by e belongs to X ; (ii) says that whenever e possesses this property, every ray directed by e and emanating from a point of X is contained in X .

Proof. If e is a recessive direction, then there exists $\bar{x} \in X$ such that $a_i^T \bar{x} + t a_i^T e = a_i^T [\bar{x} + te] \leq b_i$ for all $t > 0$ and all $i \in \mathcal{I}$, which clearly implies that $a_i^T e \leq 0$ for all i , that is, $Ae \leq 0$. Vice versa, if e is such that $Ae \leq 0$, then for every $x \in X$ and every $t \geq 0$ we have $A(x + te) = Ax + tAe \leq Ax \leq b$, that is, the ray $\{x + te : t \geq 0\}$ belongs to X . \square

Remark: The definition of an recessive direction can be straightforwardly extended from polyhedral to convex sets. The “convex analogy” of Proposition 2.3.4 states that the set of recessive directions of a nonempty closed convex set Q is a closed cone, and a ray, starting at a point of Q and directed by a recessive direction, belongs to Q .

Exercise 2.6 What is the recessive cone of the polyhedral set X shown on figure 2.1.a)? What is the recessive cone of the triangle shown on figure 2.1.b)?

The recessive cone of X is the angle between the two rays shown on fig. 2.1.c). The recessive cone of the triangle is trivial – it is the origin.

Recessive subspace and decomposition

Recall that a line ℓ in \mathbf{R}^n is an affine subspace of \mathbf{R}^n of dimension 1; this is exactly the same as to say that $\ell = \{x + te : t \in \mathbf{R}\}$ with some x and a nonzero vector e . It is easy to understand when a polyhedral set X contains lines and what are these lines:

Proposition 2.3.5 Let X be a nonempty polyhedral set given by $X = \{x : Ax \leq b\}$, see (2.3.1). Then X contains a set of the form $\{x + te : t \in \mathbf{R}\}$ if and only if $x \in X$ and $Ae = 0$. In particular,

- X contains a line, directed by vector $e \neq 0$, iff e belongs to the kernel $\text{Ker } A := \{e : Ae = 0\}$ of A , and in this case every line directed by e and passing through a point of X belongs to X .
- X contains lines iff $\text{Ker } A \neq \{0\}$, or, equivalently, iff $\text{Rec}(A) \cap [-\text{Rec}(A)] \neq \{0\}$.

Proof. The set $\{x + te : t \in \mathbf{R}\}$ belongs to X iff both the rays $\{x + te : t \geq 0\}$ and $\{x - te : t \geq 0\}$ emanating from x and directed by e and $-e$ belong to X ; by Proposition 2.3.4, this is the case iff $x \in X$ and both e and $-e$ belong to $\text{Rec}(X)$, that is, $Ae \leq 0$ and $-Ae \leq 0$, or, which is the same, $Ae = 0$. \square

In many aspects, polyhedral sets containing lines are less suited for analysis than those not containing lines. E.g., a polyhedral set containing lines definitely does not have extreme points (why?), while, as we shall see in a while, a polyhedral set not containing lines does have extreme points. Fortunately, it is easy to “get rid” of the lines.

Proposition 2.3.6 [Decomposition] A nonempty polyhedral set $X = \{x : Ax \leq b\}$, see (2.3.1), can be represented as the arithmetic sum of a linear subspace $L = \text{Ker } A$ and a nonempty polyhedral set \bar{X} which does not contain lines:

$$X = \bar{X} + \text{Ker } A. \quad (2.3.6)$$

One can take as \bar{X} the intersection $X \cap L^\perp$.

Proof. Let us set $\bar{X} = X \cap L^\perp$; we claim that this is a nonempty polyhedral set satisfying (2.3.6). Indeed, X is nonempty by assumption; with $x \in X$ and every $e \in \text{Ker } A$, the vector $x - e$ belongs to X (Proposition 2.3.5). Specifying e as the orthogonal projection of x onto L (so that $x - e$ is the

orthogonal projection \bar{x} of x onto L^\perp), we conclude that this projection belongs to X , and thus \bar{X} is nonempty and, moreover, is such that $x = \bar{x} + e \in \bar{X} + \text{Ker } A$, whence $\bar{X} + \text{Ker } A \supset X$. Since \bar{X} is nonempty, it is a polyhedral set; indeed, to get a polyhedral description of \bar{X} , one should add to the inequalities $Ax \leq b$ specifying X a system of homogeneous linear inequalities specifying L^\perp , say, the system $a_{m+i}^T x = 0$, $1 \leq i \leq \dim \text{Ker } A$, where vectors a_{m+i} , $1 \leq i \leq \dim \text{Ker } A$, span the linear subspace $\text{Ker } A$. By construction, \bar{X} is a part of X , whence $\bar{X} + \text{Ker } A \subset X$ by Proposition 2.3.5. We have already seen that $\bar{X} + \text{Ker } A \supset X$ as well, whence $\bar{X} + \text{Ker } A = X$. Finally, \bar{X} does not contain lines, since the direction e of a line in X , by Proposition 2.3.5, should be a nonzero vector satisfying the equations $a_i^T e = 0$, $i \in \mathcal{I}$, and $a_{m+i}^T e = 0$, $1 \leq i \leq \dim \text{Ker } A$; the first group of these equations says that $e \in \text{Ker } A$, and the second — that $e \in (\text{Ker } A)^\perp$, meaning that $e \in \text{Ker } A \cap (\text{Ker } A)^\perp = \{0\}$, which is impossible. \square

Proposition 2.3.6 is the first step towards our goal – describing the structure of a polyhedral set; it says that investigating this structure can be reduced to the case when the set does not contain lines. Before passing to the remaining steps, we need one more element of “equipment” – the notions of a *base* and *extreme ray* of a polyhedral cone.

2.3.4 Bases and Extreme Rays of a Polyhedral Cone

Consider a polyhedral cone

$$R = \{x \in \mathbf{R}^n : Bx \leq 0\} \quad B = \begin{bmatrix} b_1^T \\ \vdots \\ b_k^T \end{bmatrix} \in \mathbf{R}^{k \times n}. \quad (2.3.7)$$

Pointed cones. Cone (2.3.7) is called *pointed* if and only if it does not contain lines; invoking Proposition 2.3.5, this is the case if and only if $\text{Ker } B = \{0\}$, or, which is the same, there is no nonzero vector e such that $Be \leq 0$ and $B[-e] \leq 0$. Geometrically, the latter means that the only vector e such that $e \in K$ and $-e \in K$ is the zero vector. E.g., the nonnegative orthant $\mathbf{R}_+^n := \{x \in \mathbf{R}^n : x \geq 0\} = \{x : [-I]x \leq 0\}$ is pointed.

Base of a cone. Assume that the cone K given by (2.3.7) is nontrivial – does not reduce to the singleton $\{0\}$.

Consider a hyperplane Π in \mathbf{R}^n which does not pass through the origin. W.l.o.g. we can represent such a hyperplane by linear equation with unit right hand side:

$$\Pi = \{x \in \mathbf{R}^n : f^T x = 1\} \quad [f \neq 0] \quad (2.3.8)$$

It may happen that this hyperplane intersects all nontrivial rays comprising K , that is,

$$x \in K, x \neq 0 \Rightarrow \exists s \geq 0 : sx \in \Pi.$$

This is exactly the same as to say that f has positive inner products with all nonzero vectors from K (why?). When f possesses this property, the polyhedral set $Y = K \cap \Pi = \{x : Bx \leq 0, f^T x = 1\}$ is nonempty and “remembers” K :

$$K = \{x = ty : t \geq 0, y \in Y\}$$

In this situation, we shall call Y a *base* of K ; thus, a base of $K = \{x : Bx \leq 0\}$ is a nonempty set of the form

$$Y = \{x : Bx \leq 0, f^T x = 1\}$$

where f has positive inner products with all nonzero vectors from K . For example, the bases of nonnegative orthant are “produced” by strictly positive vectors f , and only by those vectors (why?)

Now, not every polyhedral cone admits a base; say, the trivial cone $\{0\}$ does not admit it. Another “bad” in this respect cone is a cone which is *not* pointed. Indeed, if K is not pointed, then, as we have already seen, there is a nonzero e such that both e and $-e$ belong to K ; but then there cannot exist a vector f forming positive inner products with all nonzero vectors from K . A useful (and even crucial, as we shall see in the sequel) fact is that the outlined two obstacles – triviality and non-pointedness – are the only obstacles to existing a base:

Proposition 2.3.7 *Let a polyhedral cone $K = \{x : Bx \leq 0\}$ in \mathbf{R}^n be nontrivial ($K \neq \{0\}$) and pointed. Then there exists $f \in \mathbf{R}^n$ such that $f^T x > 0$ for all $x \in K \setminus \{0\}$, that is, K admits a base.*

Proof. Let $K^* = \{y \in \mathbf{R}^n : y^T x \geq 0 \forall x \in K\}$ be the cone dual to K . We claim that K^* has a nonempty interior: there exists a vector f such that an Euclidean ball of certain positive radius r , centered at f , is contained in K^* . Note that this claim implies the result we seek to prove: indeed, if f is as above and $x \in K \setminus \{0\}$, then $(f - h)^T x \geq 0$ whenever $\|h\|_2 \leq r$, whence $f^T x \geq \sup_{h: \|h\|_2 \leq r} h^T x > 0$.

It remains to support our claim. Assume, on the contrary to what should be proved, that the interior of K^* is empty. Since K^* is a convex set, we conclude that $\text{Aff}(K^*)$ is less than the entire \mathbf{R}^n (Theorem 2.1.3). Since $0 \in K^*$, $\text{Aff}(K^*) \ni 0$ and thus $L = \text{Aff}(K^*)$ is a linear subspace in \mathbf{R}^n of the dimension $< n$. Thus, there exists $e \neq 0$ such that $e \in L^\perp$, whence $e^T y = 0$ for all $y \in K^*$. But then both e and $-e$ belong to $(K^*)^*$, and *the latter cone is nothing but K* (Theorem 2.2.5). Thus, K is not pointed, which is the desired contradiction. \square

The importance of the notion of a base of a cone K is that on one hand, it “remembers” K and thus bears full information on the cone, and on the other hand it is in certain respects simpler than K and thus is easier to investigate. E.g., we shall see in the mean time that a base of a cone is a *bounded* nonempty polyhedral set, and those sets admit simple description — they are convex hulls of the (nonempty and finite) sets of their vertices. For the time being, we shall prove a simpler statement:

Proposition 2.3.8 *The recessive cone of a base Y of a polyhedral cone K is trivial: $\text{Rec}(Y) = \{0\}$.*

Proof. Let $Y = \{x : Bx \leq 0, f^T x = 1\}$ be a base of a polyhedral cone $K = \{x : Bx \leq 0\}$, so that $K \neq \{0\}$ and f has positive inner products with all nonzero vectors from K . By Proposition 2.3.4, $\text{Rec}(Y) = \{e : B^T e = 0, f^T e = 0\}$; assuming that the latter set contains a nonzero vector e , we see that e is a nonzero vector from K , and this vector has zero inner product with f , which is impossible. \square

Remark: the notion of a base makes sense, and the results stated in Propositions 2.3.7 and 2.3.8 hold true for arbitrary *closed* cones, not only polyhedral ones.

Extreme rays of a polyhedral cone. Extreme rays of polyhedral cones are “cone analogies” of extreme points of polyhedral sets.

Definition 2.3.3 *Let K be a cone. A ray in K is the set of all vectors $\{tx : t \geq 0\}$, where $x \in K$; x is called a generator, or direction, of the ray. A ray is called nontrivial, if it contains nonzero vectors.*

From the definition it follows that generators of a nontrivial R are all nonzero points on this ray, so that all generators of a nontrivial ray R are positive multiples of each other.

Definition 2.3.4 [extreme ray] *An extreme ray of a cone K is a nontrivial ray $R = \{tx : t \geq 0\}$ in K with the following property: whenever a generator x of the ray is represented as $x = u + v$ with $u, v \in K$, both vectors u and v belong to R .*

Exercise 2.7 *Let K be a pointed cone and v_1, \dots, v_k be points of K . Prove that*

- 1) *If $v_1 + \dots + v_k = 0$, then $v_1 = \dots = v_k = 0$*
- 2) *If $v_1 + \dots + v_k = e$ is a generator of an extreme ray of K , then v_i , $1 \leq i \leq k$, are nonnegative multiples of e .*

Note that the notion of extreme ray is geometric — it does not refer to a particular description of the cone in question. Note also that if the property characteristic for a generator of an extreme ray holds true for one of generators of a given nontrivial ray, it automatically holds true for all other generators of the ray.

Example: A ray in the nonnegative orthant \mathbf{R}_+^n is the set comprised of all nonnegative multiples of a nonnegative vector. Nontrivial rays are comprised of all nonnegative multiples of *nonzero* nonnegative vectors. E.g., the set $\{t[1; 1; 0] : t \geq 0\}$ is a nontrivial ray in \mathbf{R}^3 (draw it!). On a closer inspection, the extreme rays of \mathbf{R}_+^n are the nonnegative parts of the n coordinate axes, that is, the rays generated by basic orths e_1, \dots, e_n . To see that, say, the ray $R_1 = \{te_1 : t \geq 0\}$ is extreme, we should take a whatever generator of the ray, e.g., e_1 , and to check that when $e_1 = u + v$ with nonnegative vectors u, v , then both u and v are nonnegative multiples of e_1 , which is evident (since from $u_i + v_i = (e_1)_i$ and $u_i, v_i \geq 0$ it follows that $u_i = v_i = 0$ when $i = 2, \dots, n$). To see that the nonnegative parts of the coordinate axes are the only extreme rays of \mathbf{R}_+^n , assume that x is a generator of an extreme ray R . Then x is a nonzero nonnegative vector. If x has at least two positive entries, say, $x_1 > 0$ and $x_2 > 0$, then we can set $x = [x_1; 0; \dots; 0] + [0; x_2; x_3; \dots; x_n]$, thus getting a decomposition of x into the sum of two nonnegative vectors which clearly are not nonnegative multiples of x . Thus, x has exactly one positive entry, and thus is a positive multiple of certain basic orth, meaning that R is the nonnegative part of the corresponding coordinate axis.

The role of extreme rays in the geometry of polyhedral cones is similar to the role of vertices in the geometry of polyhedral sets. E.g., we have already mentioned the fact we intend to prove in the sequel: *a nonempty and bounded polyhedral set is the convex hull of the (finite) set of its vertices*. The “cone analogy” of this statement reads: *A pointed and nontrivial ($K \neq \{0\}$) polyhedral cone K possesses extreme rays, their number is finite, and K is the conic hull of the (generators of the) extreme rays*. Here we present an important result on algebraic characterization of extreme rays and their relation to extreme points.

Proposition 2.3.9 *Let $K \subset \mathbf{R}^n$ be a pointed nontrivial ($K \neq \{0\}$) polyhedral cone given by (2.3.7). Then*

(ii) A nonzero vector $e \in K$ generates an extreme ray of K if and only if among the inequalities $b_i^T x \leq 0$, $i = 1, \dots, k$, defining K there are at least $n - 1$ linearly independent inequalities which are active (i.e., are equalities) at e .

(ii) Let $Y = \{x : Bx \leq 0, f^T x = 1\}$ be a base of K (note that K admits a base by Proposition 2.3.7) so that every nontrivial ray in K intersects Y . A nontrivial ray R in K is extreme if and only if its intersection with Y is an extreme point of Y .

Proof. (i): Let e generate a nontrivial ray R in K , and let I be the set of indices of vectors b_i which are orthogonal to e . We should prove that R is extreme iff among the vectors b_i , $i \in I$, there are $n - 1$ linearly independent.

In one direction: assume that the set $\{b_i : i \in I\}$ contains $n - 1$ linearly independent vectors, say, b_1, \dots, b_{n-1} , and let us prove that R is an extreme ray. Indeed, let $e = u + v$ with $u, v \in K$; we should prove that then $u, v \in R$. Since $e = u + v$, we have $b_i^T(u + v) = b_i^T e = 0$, $1 \leq i \leq n - 1$, on one hand, and $b_i^T u \leq 0$, $b_i^T v \leq 0$ due to $u, v \in K$. We conclude that $b_i^T u = b_i^T v = 0$, $1 \leq i \leq n - 1$, so that every one of the vectors u, v, e is a solution to the system of homogeneous linear equations

$$b_i^T x = 0, 1 \leq i \leq n - 1$$

in variables x . Since b_1, \dots, b_{n-1} are linearly independent, the solution set L of this system is a one-dimensional linear subspace, and since e is a nonzero vector from this linear subspace, all other vectors from L are multiples of e . In particular, $u = \lambda e$ and $v = \mu e$ with some real λ, μ . Now recall that K is pointed and $u, v, e \in K$, meaning that $\lambda \geq 0$, $\mu \geq 0$ (e.g., assuming $\lambda < 0$, we get $0 \neq u \in K$ and $-u = |\lambda|e \in K$, which is impossible). Thus, u and v are nonnegative multiples of e and thus belong to R , as claimed.

In the other direction: assume that R is an extreme ray, and let us prove that the set $\{b_i : i \in I\}$ contains $n - 1$ linearly independent vectors. Assume that the latter is not the case. Then the dimension of the linear span of the set is $\leq n - 2$, meaning that the dimension of the orthogonal complement to this linear span is ≥ 2 . Thus, the set of all vectors orthogonal to all b_i , $i \in I$, is ≥ 2 . Therefore this set (which contains e due to the origin of I) contains also a vector h which is not proportional to e . Now note that $b_i^T(e + th) = 0$ for all $i \in I$ and $b_i^T(e + th) < 0$ when $i \notin I$ and t is small enough in absolute value (since for i in question, $b_i^T e < 0$). It follows that there exists a small positive t such that $b_i^T(e \pm th) \leq 0$ for all $i = 1, \dots, k$, meaning that the vectors $u = \frac{1}{2}[e + th]$ and $v = \frac{1}{2}[e - th]$ belong to K . We clearly have $u + v = e$; since R is an extreme ray, both u and v should be nonnegative multiples of e , which, due to $t > 0$, would imply that h is proportional to e , which is not the case. We have arrived at a desired contradiction. (i) is proved.

(ii): Let $R = \{te : t \geq 0\}$ be a nontrivial ray in K ; then e is a nonzero vector from K , and from the definition of a base it follows that the ray R intersects Y at certain nonzero point e_R , which also is a generator of R . We should prove that R is an extreme ray iff e_R is an extreme point of Y .

In one direction: Let R be an extreme ray. Let us lead to contradiction the assumption that e_R is not an extreme point of Y . Indeed, under this assumption there exists a nonzero vector h such that both $e_R + h$ and $e_R - h$ belong to Y and thus belong to K . Setting $u = \frac{1}{2}[e_R + h]$, $v = \frac{1}{2}[e_R - h]$, we get $u, v \in K$ (K is a cone!) and $u + v = e_R$. Since R is an extreme ray, it follows that u and v are proportional to e_R , whence also h is proportional to e_R . The latter is impossible: since e_R and $e_R + h$ belong to Y , we have $f^T e_R = 1 = f^T(e_R + h)$, whence $f^T h = 0$; since h is nonzero and is proportional to e_R , we conclude that $f^T e_R = 0$, while in fact $f^T e_R = 1$ due to $e_R \in Y$. We have arrived at a desired contradiction.

In the other direction: Let e_R be an extreme point of Y , and let us prove that then R is an extreme ray of K . Indeed, let $e_R = u + v$ with $u, v \in K$. We should prove that in this case both v and u belong to R . Assume that this is not the case, say, u does not belong to R . Then $u \neq 0$, and thus $u \notin -R$ (since K is pointed and $u \in K$). Thus, u is not a real multiple of e_R , which combines with $e_R = u + v$ to imply that v also is not a real multiple of e_R . In particular, both u and v are nonzero, and since $u, v \in K$, we have $\bar{u} = \lambda u \in Y$ and $\bar{v} = \mu v \in Y$ for properly chosen $\lambda, \mu > 0$. From equations $f^T e_R = f^T \bar{u} = f^T \bar{v} = 1$ (given by $e_R, \bar{u}, \bar{v} \in Y$) and $f^T e_R = f^T u + f^T v$ (due to $e_R = u + v$) it follows that $\lambda f^T u = 1$, $\mu f^T v = 1$ and $f^T u + f^T v = 1$, whence $\frac{1}{\lambda} + \frac{1}{\mu} = 1$. Since λ and μ are positive, we conclude that $e_R = u + v = \frac{1}{\lambda} \bar{u} + \frac{1}{\mu} \bar{v}$ is a convex combination of the vectors \bar{u}, \bar{v} from Y , the coefficients in the combination being positive. Since e_R is an extreme point of Y , we should have $e_R = \bar{u} = \bar{v}$ (Proposition 2.3), whence u and v are proportional to e_R , which is not the case. We have arrived at a desired contradiction. \square

Corollary 2.3.2 *Let K be a nontrivial ($K \neq \{0\}$) and pointed polyhedral cone. Then the number of extreme rays in K is finite.*

Proof. Indeed, by Proposition 2.3.7, K admits a base Y ; by Proposition 2.3.9.(ii), the number of extreme rays in K is equal to the number of vertices in Y , and the latter number, by Corollary 2.3.1, is finite. \square

In fact, in the context of Corollary 2.3.2 the assumptions that K is nontrivial and pointed are redundant, by a very simple reason: neither trivial, nor non-pointed cones have extreme rays. Indeed, the trivial cone cannot have extreme rays since the latter, by definition, are nontrivial. The fact that a non-pointed cone K has no extreme rays can be verified as follows. Let $R = \{te : t \geq 0\}$ be a nontrivial ray in K , and let f be a nonzero vector such that $\pm f \in K$. If f is not proportional to e , then the vectors $u = e + f$ and $v = e - f$ belong to K due to $\pm f \in K$ and $e \in K$, and do not belong to R (since they are not proportional to e). If f is proportional to e , say, $f = \tau e$, then $\tau \neq 0$ (since $f \neq 0$). Setting $u = \frac{1}{2}[e + \frac{2}{\tau}f]$, $v = \frac{1}{2}[e - \frac{2}{\tau}f]$, we, as above, get $u, v \in K$ and $u + v = e$; at the same time, $v = \frac{1}{2}[e - \frac{2}{\tau}\tau e] = -\frac{1}{2}e$, that is, $v \notin R$. In both cases, the ray R is not extreme.

The next proposition establishes a property of extreme rays similar to the one of extreme points (cf. Proposition 2.3.3):

Proposition 2.3.10 *Let K be a polyhedral cone given by (2.3.7), and let $K_I = \{x : Bx \leq 0, b_i^T x = 0, i \in I\}$ be a face of K , which clearly is a polyhedral cone along with K . Every extreme ray of K_I is an extreme ray of K .*

Proof is left to the reader.

2.4 Structure of Polyhedral Sets

Now we are well-prepared to attack directly our goal – to prove the Theorem On Structure of Polyhedral Sets stated in the preface to this lecture.

2.4.1 First Step

We start with the following fundamental statement:

Theorem 2.4.1 *Let X be a nonempty polyhedral set, given by (2.3.1) which does not contain lines. Then*

(i) *The set $\text{Ext}(X)$ of extreme points of X is nonempty and finite, and X is the arithmetic sum of the convex hull of this set and the recessive cone of X :*

$$X = \text{Conv}(\text{Ext}(X)) + \text{Rec}(X). \quad (2.4.1)$$

(ii) *If the recessive cone of X is nontrivial ($\text{Rec}(X) \neq \{0\}$), then this cone possess extreme rays, the number of these rays is finite, and the cone is a conic hull of its extreme rays: if $R_j = \{te_j : t \geq 0\}$, $1 \leq j \leq J$, are the extreme rays of $\text{Rec}(X)$, then*

$$\text{Rec}(X) = \text{Cone}\{e_1, \dots, e_J\} := \{x = \sum_{j=1}^J \mu_j e_j : \mu_j \geq 0 \forall j\}. \quad (2.4.2)$$

(iii) *As a straightforward corollary of (i) and (ii), we get that*

$$X = \{x = \sum_{i=1}^I \lambda_i v_i + \sum_{j=1}^J \mu_j e_j : \lambda_i \geq 0, \sum_i \lambda_i = 1, \mu_j \geq 0\}. \quad (2.4.3)$$

Proof. (i): The proof is by induction in the dimension k of X (that is, the affine dimension of $M = \text{Aff}(X)$, or, which is the same, linear dimension of the linear space L to which M is parallel).

Base $k = 0$ is trivial, since in this case X is a singleton: $X = \{v\}$, and we clearly have $\text{Ext}\{X\} = \{v\}$, $\text{Rec}(X) = \{0\}$, so that $\text{Ext}\{X\}$ indeed is nonempty and finite, and (2.4.1) indeed holds true.

Inductive step $k \Rightarrow k + 1$. Assume that (i) holds true for all nonempty polyhedral sets, not containing lines, of dimension $\leq k$, and let X be a nonempty polyhedral set, not containing lines, of dimension $k + 1$. Let us prove that (i) holds true for X .

The linear subspace L parallel to $\text{Aff}(X)$ is of dimension $k + 1 \geq 1$ and thus contains a nonzero vector e . Since X does not contain lines, its recessive cone is pointed (Proposition 2.3.5); thus, either e , or $-e$ is not a recessive direction of X . Swapping, if necessary, e and $-e$, we can assume w.l.o.g. that $e \notin \text{Rec}(X)$.

Now two options are possible:

A: $-e$ is a recessive direction of X ;

B: $-e$ is *not* a recessive direction of X .

Let $\bar{x} \in X$. In order to prove that $\text{Ext}(X) \neq \emptyset$ and that $\bar{x} \in \text{Conv}(\text{Ext}(X)) + \text{Rec}(X)$, we act as follows:

In the case of A, consider the ray $R = \{x_t = \bar{x} + te : t \geq 0\}$. Since e is not a recessive direction, this ray is not contained in X , meaning that some of inequalities $a_i^T x \leq b_i$, $i \in \mathcal{I}$, are not satisfied somewhere on R . Now let us move along the ray R , starting at \bar{x} . At the beginning, we are at \bar{x} , i.e., are in X ; eventually we shall leave X , meaning that there is $\bar{t} \geq 0$ such that “at time \bar{t} the point x_t is about to leave X ”, meaning that \bar{t} is the largest $t \geq 0$ such that $x_t \in X$ for $0 \leq t \leq \bar{t}$. It is clear that $x_{\bar{t}}$ belongs to a proper face of X .

Here is “algebraic translation” of the above reasoning (which by itself appeals to geometric intuition). Since $x_0 = \bar{x} \in X$, all the inequalities $a_i^T x_t \leq b_i$, $i \in \mathcal{I}$, are satisfied at $t = 0$, and since $a_i^T x_t$ is an affine function of t , an inequality $a_i^T x_t \leq b_i$ which is violated at some $t > 0$ (and we know that such an inequality exists) is

such that the affine function of t $a_i^T x_t = a_i^T x + t a_i^T e$ is increasing with t , that is, $a_i^T e > 0$. The bottom line is that there exists i such that $a_i^T e > 0$, so that the set $I = \{i : a_i^T e > 0\}$ is nonempty. Let us set

$$\bar{t} = \min_{i \in I} \frac{b_i - a_i^T \bar{x}}{a_i^T e}, \quad (*)$$

and let $i_* \in I$ be the value of i corresponding to the above minimum. Taking into account that $a_i^T \bar{x} \leq b_i$ for all i and that $a_i^T x_t \leq b_i$ for all $t \geq 0$ whenever $i \notin I$ (why?), we conclude that $\bar{t} \geq 0$ and that $a_i^T x_{\bar{t}} \leq b_i$ for all i , and on the top of it, $a_{i_*}^T x_{\bar{t}} = b_{i_*}$. Now consider the set $\bar{X} = X_{\{i_*\}} = \{x : a_{i_*}^T x = b_{i_*}, a_i^T x \leq b_i \forall i \neq i_*\}$. This set is nonempty (it contains $x_{\bar{t}}$) and thus is a face of X . This face is proper, since otherwise $a_{i_*}^T x$ would be equal to b_{i_*} on the entire X , meaning that X is contained in the affine subspace $N = \{x : a_{i_*}^T x = b_{i_*}\}$. But then $\text{Aff}(X) \subset N$, meaning that $a_{i_*}^T x \equiv b_{i_*}$ for all $x \in M = \text{Aff}(X)$; since e belongs to the parallel to M linear subspace, the latter implies that $a_{i_*}^T e = 0$, while by construction $a_{i_*}^T e > 0$. Thus, $x_{\bar{t}}$ belongs to a *proper* face \bar{X} of X , as claimed.

Now, by Proposition 2.3.1, the dimension of \bar{X} is $< \dim X$, that is, it is at most k . Besides this, \bar{X} is a nonempty polyhedral set, and this set does not contain lines (since \bar{X} is a part of X , and X does not contain lines). Applying inductive hypothesis, we conclude that $\text{Ext}(\bar{X})$ is a finite nonempty set such that $x_{\bar{t}} \in \text{Conv}(\text{Ext}(\bar{X})) + r$ with $r \in \text{Rec}(\bar{X})$. Now, by Proposition 2.3.3, $\text{Ext}(\bar{X}) \subset \text{Ext}(X)$, and by the definition of a recessive direction, r , being recessive direction of a part of X , is a recessive direction of X . We have arrived at the following conclusion:

(!) $\text{Ext}(X)$ is nonempty (and is finite by Corollary 2.3.1) and $x_{\bar{t}} \in \text{Conv}(\text{Ext}(X)) + r$ for some $r \in \text{Rec}(X)$.

Note that our reasoning did not use yet the assumption that we are in the case A, that is, that $-e$ is a recessive direction of X ; all we use till now is that $e \in L$ is not a recessive direction of X .

Now recall that we are in the case of A, so that $-e$ is a recessive direction of X , whence

$$\bar{x} = x_{\bar{t}} - \bar{t}e \in \text{Conv}\{\text{Ext}(X)\} + r', r' = r + \bar{t}(-e).$$

Since r and $-e$ are recessive directions of X and $\text{Rec}(X)$ is a cone, we have $r' \in \text{Rec}(X)$ and thus $\bar{x} \in \text{Conv}(\text{Ext}(X)) + \text{Rec}(X)$.

In the case of B, the intermediate conclusion (!) still holds true — as we have mentioned, its validity stems from the fact that $e \in L$ is not a recessive direction of X . But now similar conclusion can be extracted from considering the ray $R_- = \{\bar{x} + t[-e] : t \geq 0\}$, which, by the exactly the same reasoning as above, “hits” certain proper face of X . Thus, now, in addition to (!), there exists $\tilde{t} \geq 0$ such that $\tilde{x}_{\tilde{t}} = \bar{x} - \tilde{t}e$ satisfies

$$\tilde{x}_{\tilde{t}} \in \text{Conv}(\text{Ext}(X)) + \text{Rec}(X),$$

or, equivalently, there exist nonnegative weights $\tilde{\lambda}_v$, $v \in \text{Ext}(X)$, summing up to 1, and a vector $\tilde{r} \in \text{Rec}(X)$ such that

$$\bar{x} - \tilde{t}e = \sum_{v \in \text{Ext}(X)} \tilde{\lambda}_v v + \tilde{r}.$$

Moreover, by (!) there exist nonnegative weights $\bar{\lambda}_v$, $v \in \text{Ext}(X)$, summing up to 1, and a vector $\bar{r} \in \text{Rec}(X)$ such that

$$\bar{x} + \bar{t}e = \sum_{v \in \text{Ext}(X)} \bar{\lambda}_v v + \bar{r}.$$

Since \bar{t} and \tilde{t} are nonnegative, we have

$$\bar{x} = \mu[\bar{x} + \bar{t}e] + (1 - \mu)[\bar{x} - \tilde{t}e]$$

with properly chosen $\mu \in [0, 1]$, so that

$$\bar{x} = \underbrace{\sum_{v \in \text{Ext}(X)} [\mu \bar{\lambda}_v + (1 - \mu) \tilde{\lambda}_v] v}_{\in \text{Conv}(\text{Ext}(X))} + \underbrace{[\mu \bar{r} + (1 - \mu) \tilde{r}]}_{\in \text{Rec}(X)}.$$

The bottom line is that in both cases A, B $\text{Ext}(X)$ is finite and nonempty and $X \subset \text{Conv}(\text{Ext}(X)) + \text{Rec}(X)$. The inverse inclusion is trivial: the polyhedral set X is convex and contains $\text{Ext}(X)$, and therefore contains $\text{Conv}(\text{Ext}(X))$, and $X + \text{Rec}(X) = X$ by Proposition 2.3.4, whence $\text{Conv}(\text{Ext}(X)) + \text{Rec}(X) \subset X$. Thus, we have proved that $X = \text{Conv}(\text{Ext}(X)) + \text{Rec}(X)$ and that $\text{Ext}(X)$ is nonempty and finite. Inductive step, and thus, the verification of Theorem 2.4.1.(i), are complete.

(ii): Assume that $\text{Rec}(X) = \{x : Ax \leq 0\}$ is a nontrivial cone. Since X does not contain lines, $\text{Rec}(X)$ is also pointed (Proposition 2.3.5). Invoking Propositions 2.3.7, $\text{Rec}(X)$ admits a base Y , which clearly is a nonempty polyhedral set. By Proposition 2.3.8, the recessive cone of Y is trivial, whence, in particular, Y does not contain lines. Applying (I) to Y , we conclude that $\text{Ext}(Y)$ is nonempty and finite, and $Y = \text{Conv}(\text{Ext}(Y)) + \text{Rec}(Y) = \text{Conv}(\text{Ext}(Y)) + \{0\} = \text{Conv}(\text{Ext}(Y))$. Further, by Proposition 2.3.9.(ii), the extreme points v_1, \dots, v_p of Y are generators of extreme rays of $\text{Rec}(X)$, and every extreme ray of $\text{Rec}(X)$ is generated by one of these extreme points; thus, $\text{Rec}(X)$ has extreme rays, and their number is finite. It remains to prove that $\text{Rec}(X)$ is the conic hull of the set of generators of its extreme rays. The validity of this statement clearly is independent of how we choose the generators; choosing them as v_1, \dots, v_p , we arrive at the necessity to prove that $\text{Rec}(X) = \text{Cone}(\{v_1, \dots, v_p\})$, that is, that every $x \in \text{Rec}(X)$ can be represented as a linear combination, with nonnegative coefficients, of v_1, \dots, v_p . There is nothing to prove when $x = 0$; if $x \neq 0$, then, by the construction of a base, $x = \lambda \bar{x}$ with $\lambda \geq 0$ and $\bar{x} \in Y$. As we have already seen, $Y = \text{Conv}(\{v_1, \dots, v_p\})$, meaning that \bar{x} is a convex combination of v_1, \dots, v_p ; but then $x = \lambda \bar{x}$ is a linear combination of v_1, \dots, v_p with nonnegative coefficients (recall that $\lambda > 0$), as claimed. (ii) is proved.

(iii) is readily given by (i) and (ii). \square

Remark: For an arbitrary nonempty closed convex X , the following analogy of Theorem 2.4.1 holds true: if X does not contain lines, then the set of extreme points of X is nonempty (but not necessary finite), and X is the arithmetic sum of $\text{Conv}(\text{Ext}(X))$ and the recessive cone of X .

Immediate corollaries

Theorem 2.4.1 readily implies a lot of important information on polyhedral sets.

Corollary 2.4.1 *The set $\text{Ext}(X)$ of vertices of a bounded nonempty polyhedral set X is nonempty and finite, and $X = \text{Conv}(\text{Ext}(X))$.*

Indeed, the recessive cone of a bounded nonempty polyhedral set clearly is trivial and, in particular, the set does not contain lines. It remains to apply Theorem 2.4.1.(i). \square

Corollary 2.4.2 *A pointed nontrivial polyhedral cone $K = \{x : Bx \leq 0\}$ has extreme rays, their number is finite, and the cone is the conic hull of (generators of) the extreme rays.*

Indeed, for a cone K we clearly have $K = \text{Rec}(K)$; when K is pointed, K is a nonempty polyhedral set not containing lines. It remains to apply Theorem 2.4.1.(ii), with K in the role of X . \square

Corollary 2.4.3 *Every nonempty polyhedral set $X \subset \mathbf{R}^n$ admits a description as follows: it is possible to point out a finite and nonempty set $\mathcal{V} = \{v_1, \dots, v_I\} \in \mathbf{R}^n$ and a finite (possibly, empty) set $\mathcal{R} = \{r_1, \dots, r_J\} \subset \mathbf{R}^n$ in such a way that*

$$X = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{R}) = \left\{x = \sum_{i=1}^p \lambda_i v_i + \sum_{j=1}^J \mu_j r_j : \lambda_i \geq 0, \sum_i \lambda_i = 1, \mu_j \geq 0\right\}. \quad (2.4.4)$$

For every representation of X of this type, it holds

$$\text{Rec}(X) = \text{Cone}(\mathcal{R}) := \left\{\sum_j \mu_j r_j : \mu_j \geq 0\right\}. \quad (2.4.5)$$

In connection with possible emptiness of \mathcal{R} , recall that according to our convention “a sum of vectors with empty set of terms equals to 0,” $\text{Cone}(\{\emptyset\}) = \{0\}$ is the trivial cone, so that (2.4.4) makes sense when $\mathcal{R} = \emptyset$ and reads in this case as $X = \text{Conv}(\mathcal{V})$.

Proof. By Proposition 2.3.6, a nonempty polyhedral set X can be represented as the sum of a nonempty polyhedral set \bar{X} not containing lines and a linear subspace L . We can find a finite set f_1, \dots, f_p which linearly spans L , so that $L = \text{Cone}(\{g_1, \dots, g_{2p}\})$, where g_1, \dots, g_p are the same as f_1, \dots, f_p , and g_{p+1}, \dots, g_{2p} are the same as $-f_1, \dots, -f_p$. By Theorem 2.4.1.(iii), we can find a nonempty finite set \mathcal{V} and a finite set \mathcal{M} such that $\bar{X} = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{M})$, so that

$$\begin{aligned} X &= \bar{X} + L = [\text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{M})] + \text{Cone}(\{g_1, \dots, g_{2p}\}) \\ &= \text{Conv}(\mathcal{V}) + [\text{Cone}(\mathcal{M}) + \text{Cone}(\{g_1, \dots, g_{2p}\})] = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{M} \cup \{g_1, \dots, g_{2p}\}) \end{aligned}$$

It remains to prove that in every representation

$$X = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{R}) \quad (*)$$

with finite nonempty $\mathcal{V} = \{v_1, \dots, v_I\}$ and finite $\mathcal{R} = \{r_1, \dots, r_J\}$, it holds $\text{Cone}(\mathcal{R}) = \text{Rec}(X)$. The inclusion $\text{Cone}(\mathcal{R}) \subset \text{Rec}(X)$ is evident (since every r_j clearly is a recessive direction of X). To prove the inverse inclusion, assume that it does not take place, that is, that there exists $r \in \text{Rec}(X) \setminus \text{Cone}(\mathcal{R})$, and let us lead this assumption to a contradiction. Since r is not a conic combination of r_1, \dots, r_J , the HFL says that there exists f such that $f^T r_j \geq 0$ for all j and $f^T r < 0$. The first of these two facts implies that the linear form $f^T x$ of x is below bounded on

X ; indeed, by (*), every point $x \in X$ is of the form $\sum_i \lambda_i v_i + \sum_j \mu_j r_j$ with nonnegative λ_i, μ_j such that $\sum_i \lambda_i = 1$, whence

$$f^T x = \sum_i \lambda_i f^T v_i + \underbrace{\sum_j \mu_j f^T r_j}_{\geq 0} \geq \sum_i \lambda_i [\min_{\ell} f^T v_{\ell}] = \min_{\ell} f^T v_{\ell} > -\infty.$$

The second fact implies that same form $f^T x$ is *not* below bounded on X . Indeed, since $r \in \text{Rec}(X)$, taking $\bar{x} \in X$, the ray $R = \{\bar{x} + tr : t \geq 0\}$ is contained in X , and since $f^T r < 0$, $f^T x$ is not bounded below on R and thus on X . We got a desired contradiction. \square

Corollary 2.4.4 *A nonempty polyhedral set X possesses extreme point iff X does not contain lines. In addition, the set of extreme points of X is finite.*

Indeed, if X does not contain lines, X has extreme points and their number is finite by Theorem 2.4.1. Now assume that X contains lines, and let $e \neq 0$ be a direction of such a line, then for every $x \in X$ the vectors $x \pm e$ belong to X (Proposition 2.3.4; note that both e and $-e$ are recessive directions of X) and thus x is not an extreme point of X . Thus, $\text{Ext}(X) = \emptyset$. \square

Remark: The first claim in Corollary is valid for every nonempty closed convex set.

Corollary 2.4.5 *Let X be a nonempty polyhedral set. Then X is bounded iff the recessive cone of X is trivial: $\text{Rec}(X) = \{0\}$, and in this case X is the convex hull of a nonempty finite set (e.g., the set $\text{Ext}(X)$).*

Indeed, if $\text{Rec}(X) \neq \{0\}$, then X contains a ray $\{\bar{x} + te : t \geq 0\}$ with $e \neq 0$; this ray, and therefore X is an unbounded set. Vice versa, if $\text{Rec}(X) = \{0\}$, then X clearly does not contain lines, and by Theorem 2.4.1.(i) $X = \text{Conv}(\text{Ext}(X))$ and $\text{Ext}(X)$ is finite and thus is bounded; the convex hull of a bounded set clearly is bounded as well, so that $\text{Rec}(X) = \{0\}$ implies that X is bounded. \square

Remark: The statement in Corollary is valid for every nonempty closed convex set.

Corollary 2.4.6 *A nonempty polyhedral set is bounded iff it can be represented as the convex hull of a finite nonempty set $\{v_1, \dots, v_p\}$. When this is the case, every vertex of X is among the points v_1, \dots, v_p .*

Indeed, if X is bounded, then $\text{Ext}(X)$ is nonempty, finite and $X = \text{Conv}(\text{Ext}(X))$ by Corollary 2.4.5. Vice versa, if a nonempty polyhedral set X is represented as $\text{Conv}(V)$, $V = \{v_1, \dots, v_N\}$, then V is nonempty, and X is bounded (since the convex hull of a bounded set clearly is bounded (why?)). Finally, if $X = \text{Conv}(\{v_1, \dots, v_N\})$ and v is a vertex of X , then $v \in \{v_1, \dots, v_N\}$ by the result of Exercise 2.3. \square

The next immediate corollary of Theorem 2.4.1 is the first major fact of the LO theory:

Corollary 2.4.7 Consider a LO program $\max_x \{c^T x : Ax \leq b\}$, and let the feasible set $X = \{x : Ax \leq b\}$ of the problem be nonempty. Then

(i) The program is bounded from above iff c has nonpositive inner products with all recessive directions of X (or, which is the same, $-c$ belongs to the cone dual to the recessive cone $\text{Rec}(X) = \{x : Ax \leq 0\}$ of X). Whenever this is the case, the program is solvable (i.e., admits an optimal solution).

(ii) If X does not contain lines (or, which is the same due to the nonemptiness of X , if $\text{Ker } A = \{0\}$, see Proposition 2.3.5) and the program is bounded from above, then among its optimal solutions there are extreme points of X .

Indeed, if c has a positive inner product with some $r \in \text{Rec}(X)$, then, taking $\bar{x} \in X$ and observing that the ray $R = \{\bar{x} + tr : t \geq 0\}$ is contained in X and that $c^T x$ is not bounded above on R (why?), the objective is not bounded above on the feasible set. Now let c have nonpositive inner products with all vectors from $\text{Rec}(X)$; let us prove that the problem is solvable. Indeed, by Corollary 2.4.3, there is a representation

$$X = \text{Conv}(\{v_1, \dots, v_I\}) + \text{Rec}(\{r_1, \dots, r_J\}) \quad (*)$$

with certain nonempty $\mathcal{V} = \{v_1, \dots, v_I\}$ and finite $\mathcal{R} = \{r_1, \dots, r_J\}$. Then, of course, $v_i \in X$ and $r_j \in \text{Rec}(X)$ for all i, j . Since every $x \in X$ can be represented as

$$x = \sum_i \lambda_i v_i + \sum_j \mu_j r_j \quad [\lambda_i \geq 0, \mu_j \geq 0, \sum_i \lambda_i = 1]$$

we have

$$c^T x = \sum_i \lambda_i c^T v_i + \underbrace{\sum_j \mu_j c^T r_j}_{\leq 0} \leq \sum_i \lambda_i c^T v_i \leq \sum_i \lambda_i [\max[c^T v_1, \dots, c^T v_I]] = \max[c^T v_1, \dots, c^T v_I].$$

We see that the objective is bounded everywhere on x by the maximum of its values at the points v_1, \dots, v_I . It follows that the best (with the largest value of the objective) of the (belonging to X !) points v_1, \dots, v_I is an optimal solution to the program. (i) is proved. To prove (ii), it remains to note that when X does not contain lines, one can take, as the above \mathcal{V} , the set of extreme points of X . \square

Remark: The fact that a feasible and bounded LO program admits an optimal solution, stated in Corollary 2.4.7.(i), is already known to us; we obtained it (via a quite different tool, the Fourier-Motzkin elimination scheme) already in Lecture 1.

Minimality of the representation stated in Theorem 2.4.1

Corollary 2.4.3 states that every nonempty polyhedral set X can be represented in the form of (2.4.4):

$$X = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{R})$$

with certain nonempty finite \mathcal{V} and finite, possibly, empty, set \mathcal{R} . When X does not contain lines, Theorem 2.4.1 states that in such a representation, one can take as \mathcal{V} the set of extreme points of X , and as \mathcal{R} — the set of generators of the extreme rays of $\text{Rec}(X)$. There are, of

course, other options: we can add to the just defined \mathcal{V} any extra point of X , and add to \mathcal{R} any vector from $\text{Rec}(X)$. It turns out, however, that the representation stated by Theorem 2.4.1 is the only “minimal” one:

Proposition 2.4.1 *Let X be a nonempty polyhedral set not containing lines, let $\mathcal{V}_* = \text{Ext}(X) = \{v_1, \dots, v_p\}$, and let $\mathcal{R}_* = \{r_1, \dots, r_q\}$ be the set of generators of the extreme rays of $\text{Rec}(X)$. Then for every representation*

$$X = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{R}), \quad (*)$$

where $\mathcal{V} = \{u_1, \dots, u_P\}$ is a nonempty finite set, and $\mathcal{R} = \{e_1, \dots, e_Q\}$ is a finite set, the following is true:

- (i) every point $v_i \in \mathcal{V}_*$ of X is one of the points u_1, \dots, u_P , and
- (ii) $\text{Cone}(\mathcal{R}) = \text{Rec}(X)$, and every vector $r_i \in \mathcal{R}_*$ is positive multiple of one of the vectors e_1, \dots, e_Q (that is, every extreme ray of $\text{Rec}(X)$, if any exists, is among the rays generated by e_1, \dots, e_Q).

Proof. (i): let v be a vertex of X , and let us prove that $v \in \mathcal{V}$. Indeed, by $(*)$ we have

$$v = \underbrace{\sum_{i=1}^P \lambda_i u_i}_u + \underbrace{\sum_{j=1}^Q \mu_j e_j}_e \quad [\lambda_j \geq 0, \mu_j \geq 0, \sum_i \lambda_i = 1]$$

We clearly have $u_i \in X$ and $e_j \in \text{Rec}(X)$ for all i, j , whence $v \in X$ and $e \in \text{Rec}(X)$. We claim that $e = 0$; indeed, otherwise we would have $v - e = u \in X$, and $v + e \in X$ due to $x \in X$ and $e \in \text{Rec}(X)$. Thus, $v \pm e \in X$ and $e \neq 0$, which is impossible for the extreme point v (see geometric characterization of extreme points, Proposition 2.3.2). Thus, $v \in \text{Conv}(\{u_1, \dots, u_P\}) \subset X$, whence v , being a vertex of X , is one of the points u_1, \dots, u_P by the result of Exercise 2.3. (i) is proved.

(ii): The fact that $\text{Cone}(\mathcal{R}) = \text{Rec}(X)$ was established in Corollary 2.4.3. It follows that if e is a generator of an extreme ray R in $\text{Rec}(X)$, then $e = \sum_{j=1}^Q \lambda_j e_j$ with some $\lambda_j \geq 0$. Since $e_j \in \text{Rec}(X)$, applying the result of Exercise 2.7.2), those of the vectors $\lambda_j e_j$ which are nonzero (and there are such vectors, since $\sum_j \lambda_j e_j = e \neq 0$) are positive multiples of e . Thus, R admits a generator which one of the vectors e_1, \dots, e_Q . \square

Note that the “minimality” result stated by Proposition 2.4.1 heavily exploits the fact that X does not contain lines. While a nonempty polyhedral set containing lines still is the sum of the convex hull of a nonempty finite set \mathcal{V} and the conic hull of a finite set \mathcal{R} , there definitely exist pairs \mathcal{V}, \mathcal{R} and $\mathcal{V}', \mathcal{R}'$ which “produce” the same set X and at the same time, say, $\mathcal{V}' \cap \mathcal{V} = \emptyset$ (and even $\text{Conv}(\mathcal{V}) \cap \text{Conv}(\mathcal{V}') = \emptyset$). What is uniquely defined by a *whatever* nonempty polyhedral set X , is the conic hull of \mathcal{R} : this is nothing but the recessive cone of X . To arrive at this conclusion, you should repeat word by word the reasoning which we used to demonstrate that $\text{Conv}(\mathcal{R}) = \text{Rec}(X)$ when proving Proposition 2.4.1.(ii).

2.4.2 Second Step

We have proved that every nonempty polyhedral set X , along with its “outer” description $X = \{x : Ax \leq b\}$, admits a simple “inner” representation: it is generated by two properly

chosen finite sets \mathcal{V} (this set is nonempty) and \mathcal{R} (this set can be empty) according to (2.4.4). What is missing yet, is the inverse statement – that every set representable in the just outlined form is polyhedral. Our local goal is to establish this missing element, thus ending up with a nice outer (solution set of a solvable system of linear inequalities) and inner (given by (2.4.4)) representation of nonempty polyhedral sets. Here is this missing element.

Theorem 2.4.2 *Let $\mathcal{V} = \{v_1, \dots, v_I\}$ be a finite nonempty subset of \mathbf{R}^n , and $\mathcal{R} = \{r_1, \dots, r_J\}$ be a finite subset of \mathbf{R}^n , and let*

$$X = \text{Conv}(\mathcal{V}) + \text{Cone}(\mathcal{R}). \quad (2.4.6)$$

Then X is a nonempty polyhedral set.

Proof. We are about to present two alternative proofs: one immediate, and another one more involving and more instructive.

Immediate proof: X clearly is nonempty and polyhedrally representable (as the image of a clearly polyhedral set $\{[\lambda; \mu] \in \mathbf{R}^I \times \mathbf{R}^J : \lambda \geq 0, \sum_i \lambda_i = 1, \mu \geq 0\}$ under the linear mapping $[\lambda; \mu] \mapsto \sum_i \lambda_i v_i + \sum_j \mu_j r_j$). By Fourier-Motzkin elimination (Theorem 1.2.1), X is a polyhedral set. \square

Alternative proof: The fact that X is nonempty is evident: $\mathcal{V} \subset X$. We can assume w.l.o.g. that $0 \in X$. Indeed, shifting all vectors from \mathcal{V} by $-v_1$, we shift by the same vector the set X given by (2.4.6), thus ensuring that the shifted X contains the origin. At the same time, a shift of a set clearly is polyhedral iff the set is so.

Now, the *polar* $\text{Polar}(Y)$ of a set $Y \subset \mathbf{R}^n$ which contains the origin is, by definition, the set of all vectors $f \in \mathbf{R}^n$ such that $f^T y \leq 1$ for all $y \in Y$.

For example (check what follows!),

- The polar of $\{0\}$ is \mathbf{R}^n , and the polar of \mathbf{R}^n is $\{0\}$
- The polar of a linear subspace L is its orthogonal complement L^\perp
- The polar of a cone is minus its dual cone.

The polar clearly is nonempty — it contains the origin.

Our plan of attack is as follows:

A. Assuming that the set X given by (2.4.6) contains the origin, we shall prove that its polar $X^* = \text{Polar}(X)$ is a nonempty polyhedral set. As such, it admits representation of the form similar to (2.4.6):

$$X^* = \text{Conv}(\mathcal{V}^*) + \text{Cone}(\mathcal{R}^*) \quad (!)$$

(\mathcal{V}^* is finite and nonempty, and \mathcal{R}^* is finite).

B. X^* clearly contains the origin and by A it admits a representation (!), whence, by the same A, the set $(X^*)^*$ is polyhedral. On the other hand, we shall prove that $(X^*)^* = X$, thus arriving at the desired conclusion that X is polyhedral.

Let us execute our plan.

A is immediate. Observe that f satisfies $f^T x \leq 1$ for all $x \in X$ iff $f^T r_j \leq 0$ for all $j \leq J$ and $f^T v_i \leq 1$ for all $i \leq I$.

Indeed, if $f^T r_j > 0$ for some j , then $f^T[v_1 + tr_j] \rightarrow +\infty$ as $t \rightarrow \infty$, and since $v_1 + tr_j \in X$ for every $t \geq 0$ due to (*), $f \notin X^*$; and of course $f \notin X^*$ when $f^T v_i > 1$ for some i , since all $v_i \in X$. Thus, if $f \in X^*$, then $f^T r_j \leq 0$ for all j and $f^T v_i \leq 1$ for all i . Vice versa, assume that $f^T r_j \leq 0$ and $f^T v_i \leq 1$ for all i ; then $f^T x \leq 1$ for all $x \in X$ by exactly the same argument as used in the proof of item (i) in Corollary 2.4.7.

Now, the above observation proves that X^* is the solution set of the system $\{r_j^T f \leq 0, 1 \leq j \leq J, v_i^T f \leq 1, 1 \leq i \leq I\}$ of linear inequalities in variables f , and since the system is solvable (e.g., 0 is its feasible solution), X^* is a nonempty polyhedral set, as stated in A.

B: all we need is to prove that the set X given by (2.4.6) is the polar of its polar: $X = (X^*)^*$. By definition of the polar, we every set is *part* of the polar of its polar, so that $X \subset (X^*)^*$. To prove equality, let us prove that $(X^*)^* \subset X$. To this end we need the following fact:

Lemma 2.4.1 *Let X be given by (2.4.6) and $y \in \mathbf{R}^n$ be such that $y \notin X$. Then there exists $f \in \mathbf{R}^n$ and $\epsilon > 0$ such that*

$$f^T y > f^T x + \epsilon \quad \forall x \in X.$$

Lemma \Rightarrow the required conclusion: Taking Lemma for granted, assume, on the contrary to what we want to prove, that there exists $\bar{x} \in (X^*)^* \setminus X$, and let us lead thus assumption to a contradiction. Indeed, applying Lemma to a vector $\bar{x} \in (X^*)^* \setminus X$, we conclude that there exists f such that $f^T \bar{x} > f^T x + \epsilon \quad \forall x \in X$. Since $0 \in X$, it follows that $0 \leq \sup_{x \in X} f^T x < f^T \bar{x} - \epsilon$. Since $\epsilon > 0$, multiplying f by an appropriate positive real we can ensure that $0 \leq \sup_{x \in X} f^T x \leq 1 < f^T \bar{x}$, meaning that $f \in X^*$ and $\bar{x}^T f > 1$; the latter is the desired contradiction, since $\bar{x} \in (X^*)^*$ and thus we should have $\bar{x}^T g \leq 1$ for all $g \in X^*$, in particular, for $g = f$.

Proof of Lemma. Consider vectors

$$v_i^+ = [v_i; 1], 1 \leq i \leq I, v_{i+j}^+ = [r_j; 0], 1 \leq j \leq J, y^+ = [y; 1]$$

in \mathbf{R}^{n+1} . We claim that y^+ is *not* a conic combination of $v_i^+, 1 \leq i \leq I + J$.

Indeed, assuming that

$$y^+ = \sum_{\ell=1}^{I+J} \lambda_\ell v_\ell^+ \quad \text{with } \lambda_\ell \geq 0,$$

and looking at the last coordinates of all vectors involved, we get $1 = \sum_{i=1}^I \lambda_i$; looking at the first $n-1$ coordinates, we conclude that $y = \sum_{i=1}^I \lambda_i v_i + \sum_{j=1}^J \lambda_{I+j} r_j$. The bottom line is that y is a convex combination of v_1, \dots, v_I plus a conic combination of r_1, \dots, r_J , that is, $y \in X$ by (2.4.6), which is not the case.

Now, since y^+ is not a conic combination of v_1^+, \dots, v_{I+J}^+ , the HFL says to us that there exists $f^+ = [f; \alpha]$ such that $f^T y + \alpha = [f^+]^T y^+ =: \epsilon > 0$, while $[f^+]^T v_\ell^+ \leq 0, 1 \leq \ell \leq I + J$. In other words, $f^T v_i \leq -\alpha$ and $f^T r_j \leq 0$ for all i, j . Now, if $x \in X$, then by (2.4.6) we have

$$x = \sum_i \lambda_i v_i + \sum_j \mu_j r_j$$

for certain $\lambda_j \geq 0$ summing up to 1 and $\mu_j \geq 0$. It follows that

$$f^T x = \sum_i \lambda_i f^T v_i + \sum_j \mu_j f^T r_j \leq \sum_i \lambda_i [-\alpha] + \sum_j \mu_j \cdot 0 = -\alpha.$$

The bottom line is that $f^T x \leq -\alpha$ everywhere on x , while $f^T y = -\alpha + \epsilon$ with $\epsilon > 0$, that is, $f^T x + \epsilon \leq f^T y$ for all $x \in X$, as claimed in Lemma. \square

Note that in the case of a polyhedral set $X = \{x : A^T x \leq b\}$ the result stated by Lemma 2.4.1 is evident: if $y \notin X$, then there exists a row a_i^T of A such that $a_i^T y > b_i$, while $a_i^T x \leq b_i$ everywhere on X . In contrast to this, Lemma 2.4.1 is a by far non-evident and powerful statement (which, on a closest inspection, inherited its power from the HFL) – it provides us with a separation-type result at time when we do not know whether the set X in question is or is not polyhedral.

Separation Theorem for Convex Sets

The new for us “driving force” in the previous proof – Lemma 2.4.1 – admits a far-reaching extension onto general convex sets, which is the “in particular” part in Theorem 2.4.3 we are about to present. We start with the following

Definition 2.4.1 *Let X, Y be two nonempty sets in \mathbf{R}^n . We say that a linear function $e^T x$ separates these sets, if the function is non-constant on $X \cup Y$ and everywhere on X is \geq than every everywhere on Y , that is, $e^T x \geq e^T y$ whenever $x \in X$ and $y \in Y$.*

Equivalent definition of separation if (check equivalency!):

e separates X and Y iff

$$\inf_{x \in X} e^T x \geq \sup_{y \in Y} e^T y \quad \& \quad \sup_{x \in X} e^T x > \inf_{y \in Y} e^T y. \quad (2.4.7)$$

We need also the notion of the *relative interior* of a nonempty set $X \subset \mathbf{R}^n$. The definition is as follows: a point $x \in X$ is called a *relative interior point* of X , if there exists $r > 0$ such that the intersection of the ball of radius r centered at x with the affine span of X is contained in X :

$$\exists r > 0 : y \in \text{Aff}(X), \|y - x\|_2 \leq r \Rightarrow y \in X.$$

The set of all relative interior points of X is called the *relative interior* of X (notation: $\text{rint } X$). We already know that the relative interior of a nonempty convex set X is nonempty (Proposition 2.1.3); it is easily seen (check it!) that in this case $\text{rint } X$ is convex and is *dense* in X , meaning that every point $x \in X$ is the limit of an appropriately chosen sequence of points from $\text{rint } X$.

The Separation Theorem for Convex Sets, which is an extremely powerful (if not *the* most powerful) tool of Convex Analysis, reads:

Theorem 2.4.3 *Let X, Y be nonempty convex sets in \mathbf{R}^n . These sets can be separated iff their relative interiors do not intersect.*

In particular, if Y is a nonempty closed convex set in \mathbf{R}^n and $x \in \mathbf{R}^n$ does not belong to X , then there exists a linear form which strictly separates x and Y :

$$e^T x > \sup_{y \in Y} e^T y.$$

Proof. While we usually do not prove “convex extensions” of our polyhedral results, we cannot skip the proof of the Separation Theorem, since we will use this result when speaking about Conic Duality. The proof is easy — the major part of the task “sits” already in Lemma 2.4.1.

1⁰. *Separating a point and a convex set not containing this point.* Let us prove that if x is a singleton and Y is a nonempty convex set which does not contain x , then $X = \{x\}$ and Y can be separated. By shifting x and Y by the same vector, which of course does not affect neither the premise ($x \notin Y$), nor the conclusion (" x and Y can be separated") of the statement we are proving, we can assume w.l.o.g. that $0 \in Y$. The claim is easy to verify when $x \notin \text{Aff}(Y)$. Indeed, since $0 \in Y$, $\text{Aff}(Y)$ is a linear subspace; when $x \notin Y$, taking, as e , the orthogonal projection of x onto the orthogonal complement to this linear space, we get $e^T x = e^T e > 0$ and $e^T y = 0$ for all $y \in \text{Aff}(Y) \supset Y$, as required in (2.4.7). Now let $x \in \text{Aff}(Y)$. Replacing, if necessary, \mathbf{R}^n with $\text{Lin}(Y) = \text{Aff}(Y)$, we can assume w.l.o.g. that $\text{Aff}(Y) = \text{Lin}(Y) = \mathbf{R}^n$. Now let y_1, y_2, \dots be a sequence of vectors from Y which is dense in Y , meaning that every point in Y is the limit of certain converging subsequence of $\{y_i\}_{i=1}^\infty$; the existence of such a dense sequence $\{y_i \in Y\}$ for a nonempty set $Y \in \mathbf{R}^n$ is the standard and simple fact of Real Analysis (it is called *separability of \mathbf{R}^n*). Now, let $Y_k = \text{Conv}\{y_1, \dots, y_k\}$, $k = 1, 2, \dots$. Since Y is convex and $x \notin Y$, $x \notin Y_k$, whence, by Lemma 2.4.1, for every k there exists a linear form e_k which strictly separates x and Y_k :

$$e_k^T x > \sup_{y \in Y} e_k^T y. \quad (!)$$

we clearly have $e_k \neq 0$, and since (!) remains intact when e_k is multiplied by a positive real, we can assume w.l.o.g. that $\|e_k\|_2 = 1$. Now, a sequence of unit vectors in \mathbf{R}^n always contains a converging subsequence, and the limit of this subsequence is a unit vector; thus, we can extract from $\{e_k\}$ a subsequence $\{e_{k_i}\}_{i=1}^\infty$ converging to certain unit vector e . For every i , the vector y_i belongs to all but finitely many sets Y_k , whence the inequality

$$e_{k_j}^T x \geq e_{k_j}^T y_i$$

holds true for all but finitely many values of j . Passing to limit as $j \rightarrow \infty$, we get

$$e^T x \geq e^T y_i$$

for all i , and since $\{y_i\}_{i=1}^\infty$ is dense in Y , we conclude that $e^T x \geq e^T y$ for all $y \in Y$. All what remains to check in order to conclude that the linear form given by e separates $\{x\}$ and Y , is that $e^T z$ is not constant on $\{x\} \cup Y$, which is immediate: e by construction is a unit vector, and Y is full-dimensional, so that $e^T z$ is non-constant already on Y .

2⁰. *Separating two non-intersecting nonempty convex sets.* Let now X and Y be non-intersecting convex sets. In order to separate them, we note that the set $Y - X = \{y - x : y \in Y, x \in X\}$ is nonempty and convex and does not contain the origin (the latter – since X and Y do not intersect). By the previous item, we can separate 0 and $Y - X$, that is, there exists e such that

$$0 = e^T 0 \geq e^T (y - x) \quad \forall (x \in X, y \in Y) \quad \& \quad 0 > \inf\{e^T (y - x) : y \in Y, x \in X\}$$

which is nothing but (2.4.7).

3⁰. *Separating two nonempty convex sets with non-intersecting relative interiors.* Let X and Y be nonempty convex sets with non-intersecting relative interiors. As it was mentioned, $\text{rint } X$ and $\text{rint } Y$ are convex nonempty sets, so that they can be separated by previous item: there exists e such that

$$\inf_{x \in \text{int } X} e^T x \geq \sup_{y \in \text{int } Y} e^T y \quad \& \quad \sup_{x \in \text{int } X} e^T x > \inf_{y \in \text{int } Y} e^T y$$

Since the relative interior of a convex set is dense in this set, the sup and inf in the above relation remain intact when the relative interiors of X and Y are replaced with A , Y themselves, so that separating the relative interiors of X , Y , we automatically separate X and Y .

⁴⁰ We have proved that *if* the relative interiors of nonempty convex sets do not intersect, *then* the sets can be separated. The inverse statement is nearly evident. Indeed, assume that $\text{rint } X \cap \text{rint } Y \neq \emptyset$, and let us lead to a contradiction the assumption that X and Y can be separated. Let e separate X and Y , and let $a \in \text{rint } X \cap \text{rint } Y$. By the first inequality in (2.4.7), the linear function $e^T x$ everywhere on X should be $\geq e^T a$ (since $a \in Y$), and since $a \in X$, a should be a minimizer of $e^T x$ on X . But a linear function $f^T w$ can attain its minimum on a set Z at a point z of the relative interior of this set only when the function is constant on the set.

Indeed, by definition of a relative interior point, Z contains the intersection D of $\text{Aff}(Z)$ with a ball of positive radius, so that restricted on D , the linear function in question should attain its minimum on D at the center z of D . The latter is possible only when the function is constant on D , since D is symmetric w.r.t. z . When $f^T w$ is constant on D , then $f^T h$ is constant on $D - z$, and the latter set is a centered at the origin ball of positive radius in the linear space L to which $\text{Aff}(Z)$ is parallel. Thus, f should be orthogonal to all small enough vectors from L , and thus should be orthogonal to the entire L , whence $f^T w$ is constant on $\text{Aff}(Z)$.

We see that the function $e^T y$ is constant, and equal to $e^T a$, on the entire $\text{Aff}(X)$ and thus on the entire X . By “symmetric” reasoning, $e^T y$ attains its maximum on Y and the point $a \in \text{rint } Y$, whence $e^T y$ is identically equal to $e^T a$ on Y . We see that $e^T w$ is constant on $X \cup Y$, which contradicts the origin of e . Thus, the convex sets with intersecting relative interiors cannot be separated.

⁵⁰ It remains to prove the “in particular” part of the Separation Theorem. When $x \notin Y$ and Y is nonempty, closed and convex, then there exists $r > 0$ such that the ball B of radius r centered at x does not intersect Y (why?). Applying the already proved part of Separation Theorem to $X = B$ and Y , we get a nonzero (why?) vector e such that

$$\inf_{x' \in B} e^T x' \geq \max_{y \in Y} e^T y.$$

Taking into account that the left hand side inf is $e^T x - r\|e\|_2$ (why?), we see that e strongly separates $\{x\}$ and Y . \square

Remark: A mathematically oriented reader could notice that when proving Separation Theorem for Convex Sets, we entered a completely new world. Indeed, aside of this proof and the last section in lecture 1 *all our constructions were purely rationally algebraic* – we never used square roots, exponents, convergence, facts like “every bounded sequence of reals/vectors admits extracting a subsequence which has a limit,” etc. More specifically, all our constructions, proofs and results would remain intact if we were

- replacing our “universes” \mathbf{R} and \mathbf{R}^n with the field of rational numbers \mathbf{Q} and the vector space \mathbf{Q}^n of n -dimensional vectors with rational coordinates, the linear operations being vector addition and multiplication of vectors by *rational* scalars,
- replacing polyhedral sets in \mathbf{R}^n – sets of real vectors solving finite systems of nonstrict linear inequalities with real coefficients – with their “rational” counterparts – sets of rational vectors solving finite systems of linear inequalities with rational coefficients;

- allowing for *rational* rather than real scalars when speaking about linear/convex/conic combinations and in all other places where we use operations involving scalars.

In fact, aside of the last section in lecture 1 and the story about Separation Theorem for Convex Sets, we could use in the role of our basic field of scalars \mathbf{R} not only the field of rational numbers \mathbf{Q} , but every *sub-field* of \mathbf{R} – a nonempty subset of \mathbf{R} which does not reduce to $\{0\}$ and is closed w.r.t. the four arithmetic operations. Different from \mathbf{Q} and \mathbf{R} examples of sub-fields are, say, real numbers which can be represented as $p + r\sqrt{2}$ with rational p, q , or *algebraic numbers* – reals which are roots of algebraic polynomials with rational coefficients.

Note that we will follow the “fully rationally algebraic” approach till the concluding lectures on Ellipsoid Method and Conic Programming/Interior Point algorithms, where working with reals becomes a must. In particular, till then we will not use neither Theorem 2.4.3, nor the approximation results from section 1.3.

2.4.3 Immediate Corollaries

Theorem 2.4.2 allows us to “complete” some of the results we already know. For example,

1. Corollary 2.4.1 tells us that a *nonempty bounded polyhedral set X is the convex hull of a nonempty finite set* (e.g., the set $\text{Ext}(X)$). Theorem 2.4.2 adds to this that the inverse also is true: *the convex hull of a finite nonempty set is a nonempty (and clearly bounded) polyhedral set.*
2. Corollary 2.4.2 tells us that every pointed and nontrivial polyhedral cone is the conic hull of a nonempty finite set. Clearly, the trivial cone also is the conic hull of a nonempty finite set (specifically, the singleton $\{0\}$), same as it is the conic hull of the empty set. Taking into account that every polyhedral cone is the sum of a linear subspace and a pointed polyhedral cone (this is an immediate corollary of Proposition 2.3.6), we conclude that *every polyhedral cone is the conic hull of a finite, perhaps empty, set.* Theorem 2.4.2 adds to this that the inverse also is true: *The conic hull of a finite set $\{r_1, \dots, r_j\}$ is a polyhedral cone* (look what is given by (2.4.6) when $\mathcal{V} = \{0\}$).
3. Corollary 2.4.3 says that *every nonempty polyhedral set admits representation (2.4.6).* Theorem 2.4.2 says that the inverse also is true.

In addition, Theorems 2.4.1 and 2.4.2 allow us to make the following important conclusion (which we will enrich in section 3.3.3):

If X is a polyhedral set containing the origin, so is its polar $\{y : y^T x \leq 1 \forall x \in X\}$, and X is the polar of its polar.

We have proved this statement when proving Theorem 2.4.2 (check it!)

It is very instructive to look how the inner and the outer representations of a polyhedral set, or, if you prefer, Theorems 2.4.1 and 2.4.2 complement each other when justifying different facts about polyhedral sets. E.g., using inner representations of the operand(s), it is immediate to justify the claims that the arithmetic sum of polyhedral sets or an affine image of such a set are polyhedral; this task looks completely intractable when using the outer descriptions of the operands (recall that when carrying out the latter task in section 1.2.2, we “used a cannon” — the Fourier-Motzkin elimination scheme). Similarly, with the outer descriptions, it is absolutely clear that the intersection of two polyhedral sets, or the inverse affine image of such a set, are polyhedral, while inner descriptions give absolutely no hint why these operations preserve polyhedrality.

Lecture 3

Theory of Systems of Linear Inequalities and Duality

With all due respect to the results on polyhedral sets we became acquainted with, there still are pretty simple questions about these sets (or, which is basically the same, about finite systems of linear inequalities) which we do not know how to answer. Examples of these questions are:

- How to recognize whether or not a polyhedral set $X = \{x : Ax \leq b\}$ is empty?
- How to recognize that a polyhedral set is bounded/unbounded?
- How to recognize whether or not two polyhedral sets $X = \{x : Ax \leq b\}$ and $X' = \{x : A'x \leq b'\}$ coincide with each other? More generally, With X, X' as above, how to recognize that $X \subset X'$?
- How to recognize whether or not a given LO program is feasible/bounded/solvable?

This list can be easily extended...

Now, there are two ways to pose and to answer questions like those above:

A. [Descriptive approach] One way is to ask what are “easy to certify” necessary and sufficient conditions for a candidate answer to be valid. E.g., it is easy to certify that the solution set $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ of a system of linear inequalities $Ax \leq b$ is nonempty – a certificate is given by any feasible solution to the system. Given a candidate certificate of this type — a vector $x \in \mathbf{R}^n$ – it is easy to check whether it is a valid certificate (plug x into the system and look whether it becomes satisfied); if it is so, the system definitely is solvable. And of course vice versa – if the system is solvable, this property can be certified by a just outlined certificate. In contrast to this, it is unclear how to certify that the solution set of a system $Ax \leq b$ is empty, which makes the question “whether $X = \{x : Ax \leq b\}$ is or is not empty” difficult.

B. [Operational approach] After we know *what* are “simple” certificates for candidate answers to the question under consideration, it is natural to ask *how to generate* appropriate certificates. For example, we know what is a simple certificate for nonemptiness of the solution set of a system $Ax \leq b$ — this is (any) feasible solution to this system. This being said, it is unclear how to build such a certificate given the system, even when it is known in advance that such a certificate exists.

In this lecture, we focus on **A**; specifically, we will find out what are simple certificates for various properties of polyhedral sets. The questions of how to build the certificates (which, essentially, is an algorithmic question) will be answered in the part of the course devoted to LO algorithms.

3.1 General Theorem on Alternative

3.1.1 GTA: Formulation, Proof, Different Versions

Consider a general finite system of m linear inequalities, strict and non-strict, in variables $x \in \mathbf{R}^n$. Such a system always can be written down in the form

$$a_i^T x \begin{cases} < b_i, & i \in I \\ \leq b_i, & i \in \bar{I} \end{cases} \quad (\mathcal{S})$$

where $a_i \in \mathbf{R}^n$, $b_i \in \mathbf{R}$, $1 \leq i \leq m$, I is certain subset of $\{1, \dots, m\}$, and \bar{I} is the complement of I in $\{1, \dots, m\}$.

The fact that (\mathcal{S}) is a “universal” form of a finite system of strict and nonstrict linear inequalities and linear equations is evident: a linear inequality $a^T x = b$ can be equivalently represented by the system of two opposite inequalities $a^T x \leq b$ and $a^T x \geq b$, thus we can think that our system is comprised of inequalities only; every one of these inequalities can be written in the form $a^T x \Omega b$, where Ω is a relation from the list $<, \leq, \geq, >$. Finally, we can make the signs Ω of all inequalities either \leq , or $<$, by replacing an inequality of the form $a^T x > b$ ($a^T x \geq b$) by its equivalent $[-a]^T x < [-b]$ ($[-a]^T x \leq [-b]$).

In what follows we assume that the system is nonempty, otherwise all kinds of questions about the system become trivial: an empty system of equations is solvable, and its solution set is the entire \mathbf{R}^n .

The most basic descriptive question about (\mathcal{S}) is whether or not the system is solvable. It is easy to certify that (\mathcal{S}) is solvable: as we have already explained, any feasible solution is a certificate. A much more difficult question is how to certify that the system is *unsolvable*¹. In Mathematics, the typical way to prove impossibility of something is to assume that this something does take place and then to lead this assumption to a contradiction. It turns out that finite systems of linear inequalities are simple enough to allow for unified — and extremely simple — scheme for leading the assumption of solvability of the system in question to a contradiction. Specifically, assume that (\mathcal{S}) has a solution \bar{x} , and let us try to lead this assumption to a contradiction by “linear aggregation of the inequalities of the system,” namely, as follows. Let λ_i , $1 \leq i \leq m$, be *nonnegative* “aggregation weights.” Let us multiply the inequalities of the system by scalars λ_i and sum up the results. We shall arrive at the “aggregated inequality”

$$[\sum_i \lambda_i a_i]^T x \Omega \sum_i \lambda_i b_i, \quad (3.1.1)$$

where the sign Ω of the inequality is either $<$ (this is the case when at least one strict inequality in (\mathcal{S}) gets a positive weight, i.e., $\lambda_i > 0$ for some $i \in I$), or \leq (this is the case when $\lambda_i = 0$ for all $i \in I$). Due to its origin and due to the elementary properties of the relations “ \leq ” and “ $<$ ”

¹In real life, it was realized long ago that certifying a *negative* statement is, in general, impossible. Say, a French-speaking man can easily certify his knowledge of language: he can start speaking French, thus proving his knowledge to everybody who speaks French. But how could a man certify that he does *not* know French? The consequences of understanding that it is difficult or impossible to certify negative statements are reflected in rules like “a person is not guilty until proved otherwise,” and this is why in the court of law the accused is not required to certify the negative statement “I did not commit this crime;” somebody else is required to prove the positive statement “the accused did commit the crime.”

between reals, the aggregated inequality (3.1.1) is a *consequence* of the system – it is satisfied at every solution to the system. It follows that *if the aggregated inequality has no solutions at all, then so is the system* (\mathcal{S}) . Thus, every collection λ of aggregation weights $\lambda_i \geq 0$ which results in unsolvable aggregated inequality (3.1.1), can be considered as a *certificate of insolvability* of (\mathcal{S}) .

Now, it is easy to say when the aggregated inequality (3.1.1) has no solutions at all. First, the vector of coefficients $\sum_i \lambda_i a_i$ of the variables should be zero, since otherwise the left hand side with properly chosen x can be made as negative as you want, meaning that the inequality is solvable. Now, whether the inequality $0^T x \Omega a$ is or is not solvable, it depends on what is Ω and what is a . When $\Omega = "<"$, this inequality is unsolvable iff $a \leq 0$, and when $\Omega = "\leq"$, it is unsolvable iff $a < 0$. We have arrived at the following simple

Proposition 3.1.1 *Assume that one of the systems of linear inequalities*

$$(I): \quad \begin{cases} \lambda_i \geq 0, 1 \leq i \leq m \\ \sum_{i \in I} \lambda_i > 0 \\ \sum_{i=1}^m \lambda_i a_i = 0 \\ \sum_{i=1}^i \lambda_i b_i \leq 0 \end{cases}, \quad (II): \quad \begin{cases} \lambda_i \geq 0, 1 \leq i \leq m \\ \sum_{i \in I} \lambda_i = 0 \\ \sum_{i=1}^m \lambda_i a_i = 0 \\ \sum_{i=1}^i \lambda_i b_i < 0 \end{cases} \quad (3.1.2)$$

in variables λ is solvable. Then system (\mathcal{S}) is unsolvable.

Indeed, if λ solves (I), then, aggregating the inequalities in (\mathcal{S}) with the weights λ_i , one gets a contradictory inequality of the form $0^T x < \text{"something nonpositive"}$. When λ solves (II), the same aggregation results in a contradictory inequality of the form $0^T x \leq \text{"something negative"}$. In both cases, (\mathcal{S}) admits a consequence which is a contradictory inequality (i.e., inequality with no solutions), whence (\mathcal{S}) itself has no solutions. \square

Remark 3.1.1 *Both systems in (3.1.2) are homogeneous, and therefore their solvability/insolvability is equivalent to solvability/insolvability of their “normalized” versions*

$$(I') \quad \begin{cases} \lambda_i \geq 0, 1 \leq i \leq m \\ \sum_{i \in I} \lambda_i \geq 1 \\ \sum_{i=1}^m \lambda_i a_i = 0 \\ \sum_{i=1}^i \lambda_i b_i \leq 0 \end{cases}, \quad (II') : \quad \begin{cases} \lambda_i \geq 0, 1 \leq i \leq m \\ \sum_{i \in I} \lambda_i = 0 \\ \sum_{i=1}^m \lambda_i a_i = 0 \\ \sum_{i=1}^i \lambda_i b_i \leq -1 \end{cases}$$

which contain only equalities and nonstrict inequalities. Thus, Proposition 3.1.1 says that if either (I') , or (II') is solvable, then (\mathcal{S}) is unsolvable.

One of the major results of the LO theory is that the simple *sufficient* condition for insolvability of (\mathcal{S}) stated by Proposition 3.1.1 is in fact *necessary and sufficient*:

Theorem 3.1.1 [General Theorem on Alternative] *A finite system (\mathcal{S}) of linear inequalities is unsolvable if and only if it can be led to a contradiction by admissible ($\lambda \geq 0$) aggregation. In other words, system (\mathcal{S}) of linear inequalities in variables x has no solutions iff one of the systems (I), (II) of linear inequalities in variables λ has a solution.*

Postponing the proof of GTA, we see that both solvability and *insolvability* of (\mathcal{S}) admit simple certificates: to certificate solvability, it suffices to point out a feasible solution x to the system; to certify insolvability, it suffices to point out a feasible solution λ to either (I) or (II). In both

cases, (\mathcal{S}) possesses the certified property iff an indicated certificate exists, and in both cases it is easy to check whether a candidate certificate is indeed a certificate.

Proof of GTA. Proposition 3.1.1 justifies the GTA in one direction – it states that *if* either (I), or (II), or both the systems, are solvable, *then* (\mathcal{S}) is insolvable. It remains to verify that the inverse also is true. Thus, assume that (\mathcal{S}) has no solutions, and let us prove that then at least one of the systems (I), (II) has a solution. Observe that we already know that this result takes place in the special case when all inequalities of the system are homogeneous (i.e., $b = 0$) and the system contains exactly one strict inequality, let it be the first one. Indeed, if the system of the form

$$p_1^T x < 0, p_2^T x \leq 0, \dots, p_k^T x \leq 0 \quad (S)$$

with $k \geq 1$ inequalities has no solutions, then the homogeneous linear inequality $p_1^T x \geq 0$ is a consequence of the system of homogeneous linear inequalities $-p_2^T x \geq 0, -p_3^T x \geq 0, \dots, -p_k^T x \geq 0$. By HFL, in this case there exist nonnegative $\lambda_2, \dots, \lambda_k$ such that $p_1 = \sum_{i=2}^k \lambda_i [-p_i]$, or, setting $\lambda_1 = 1$,

$$\lambda_i \geq 0, 1 \leq i \leq k, \sum_{i=1}^k \lambda_i p_i = 0.$$

We see that λ solves system (I) associated with (S) .

Now let us derive GTA from the above particular case of it. To this end, given system (\mathcal{S}) , consider the following system of homogeneous linear inequalities in variables x, y, z (y, z are scalar variables):

$$\begin{aligned} (a) \quad & -z < 0 \\ (b) \quad & a_i^T x - b_i y + z \leq 0, i \in I \\ (c) \quad & a_i^T x - b_i y \leq 0, i \in \bar{I} \\ (d) \quad & z - y \leq 0 \end{aligned} \quad (3.1.3)$$

We claim that this system is insolvable. Indeed, assuming that this system has a solution $[x; y; z]$, we have $z > 0$ by (a), whence $y > 0$ by (d). Setting $x' = y^{-1}x$ and dividing (b) and (c) by y , we get

$$a_i^T x' - b_i \leq -(z/y) < 0, i \in I, \quad a_i^T x - b_i \leq 0, i \in \bar{I},$$

that is, x' solves (\mathcal{S}) , which is impossible, since we are under the assumption that (\mathcal{S}) is insolvable.

Now, system (3.1.3) is in the form of (S) , whence, as we have seen, it follows that there exist nonnegative $\lambda_0, \dots, \lambda_{m+1}$ with $\lambda_0 = 1$ such the combination of the right hand sides in (3.1.3) with coefficients $\lambda_0, \dots, \lambda_{m+1}$ is identically zero. This amounts to

$$\begin{aligned} (a) \quad & \sum_{i=1}^m \lambda_i a_i = 0 && [\text{look at the coefficients at } x] \\ (b) \quad & \sum_{i=1}^m \lambda_i b_i = -\lambda_{m+1} && [\text{look at the coefficients at } y] \\ (c) \quad & \sum_{i \in I} \lambda_i + \lambda_{m+1} = 1 && [\text{look at the coefficients at } z] \end{aligned} \quad (3.1.4)$$

Recalling that $\lambda_1, \dots, \lambda_{m+1}$ are nonnegative, we see that

- in the case of $\lambda_{m+1} > 0$, (3.1.4.a,b) say that $\lambda_1, \dots, \lambda_m$ solve (II);
- in the case of $\lambda_{m+1} = 0$, (3.1.4.a,b,c) say that $\lambda_1, \dots, \lambda_m$ solve (I).

Thus, in all cases either (I), or (II) is solvable. □

Several remarks are in order.

A. There is no necessity to memorize the specific forms of systems (I), (II); what you should memorize, is the *principle* underlying GTA, and this principle is pretty simple:

A finite system of linear equations and (strict and nonstrict) inequalities has no solutions if and only if one can lead it to contradiction by admissible feasible aggregation of the inequalities of the system that is, by assigning the inequalities weights which make it legitimate to take the weighted sum of the inequalities and make this weighted sum a contradictory inequality.

In this form, this principle is applicable to every system, not necessary to one in the standard form (\mathcal{S}). What does it actually mean that the aggregated inequality is contradictory, it depends on the structure of the original system, but in all cases it is straightforward to understand what “contradictory” means and thus it is straightforward to understand how to certify insolvability.

For example, the recipe to realize that the system

$$\begin{array}{rcl} x_1 + x_2 & > & 0 \\ x_1 - x_2 & = & 3 \\ 2x_1 & \leq & 2 \end{array}$$

is insolvable is as follows: let us multiply the first inequality by a nonnegative weight λ_1 , the second equality — by a *whatever* weight λ_2 , and the third inequality - by a nonpositive weight λ_3 ; then it is legitimate to sum the resulting relations up, arriving at

$$\lambda_1[x_1 + x_2] + \lambda_2[x_1 - x_2] + \lambda_3[2x_1] \Omega \lambda_1 \cdot 0 + \lambda_2 \cdot 3 + \lambda_3 \cdot 2 \quad (*)$$

where Ω is “ $>$ ” when $\lambda_1 > 0$ and Ω is “ \geq ” when $\lambda_1 = 0$. Now let us impose on λ ’s the requirement that the left hand side in the aggregated inequality as a function x_1, x_2 is identically zero. Adding to this the above restrictions on the signs of λ_i ’s, we arrive at the system of restrictions on λ , specifically,

$$\begin{array}{l} \lambda_1 + \lambda_2 + 2\lambda_3 = 0 \\ \lambda_1 - \lambda_2 = 0 \\ \lambda_1 \geq 0, \lambda_3 \leq 0 \end{array} \quad (!)$$

which expresses equivalently the fact that the aggregation is “legitimate” and results in identically zero left hand side in the aggregated inequality (*). The next step is to consider separately the cases where $\Omega = “>”$ and $\Omega = “\geq”$. The first case takes place when $\lambda_1 > 0$, and here, under assumption (!), (*) reads $0 > 3\lambda_2 + 2\lambda_3$; thus, here the fact that the aggregated inequality is contradictory boils to

$$\lambda_1 > 0, 3\lambda_2 + 2\lambda_3 \geq 0. \quad (a)$$

we get a system of constraints on λ such that its feasibility implies insolvability of the original system in x -variables. The second case to be considered is that $\Omega = “\geq”$, which corresponds to $\lambda_1 = 0$; here the aggregated inequality, under assumption (!), reads $0 \geq 3\lambda_2 + 2\lambda_3$, thus, in the case in question the fact that the aggregated inequality is contradictory boils up to

$$\lambda_1 = 0, 3\lambda_2 + 2\lambda_3 > 0 \quad (b)$$

Now, GTA says the original system in x -variables is insolvable iff augmenting (!) by either (a), or (b), we get a solvable system of constraints on λ . Since the system (!) implies that $\lambda_1 = \lambda_2 = -\lambda_3$, and thus $3\lambda_2 + 2\lambda_3 = -\lambda_3$, these augmentations are equivalent to

$$\lambda_3 < 0$$

and

$$\lambda_3 = 0, -\lambda_3 > 0.$$

The first system clearly is solvable, meaning that the original system in variables x is insolvable; as an insolvability certificate, one can use $\lambda_3 = -1, \lambda_1 = \lambda_2 = -\lambda_3 = 1$.

B. It would be easier to use the GTA if we knew in advance that one of the systems (I), (II), e.g., (II), is insolvable, thus implying that (\mathcal{S}) is insolvable iff (I) is solvable. Generic cases of this type are as follows:

- *There are no strict inequalities in (\mathcal{S}) .* In this case (I) definitely is insolvable (since the strict inequality in (I) clearly is impossible), and thus (\mathcal{S}) is insolvable iff (II) is solvable;
- *The subsystem of \mathcal{S} comprised of all nonstrict inequalities in (\mathcal{S}) is solvable.* In this case, (II) definitely is insolvable²; thus, (\mathcal{S}) is insolvable iff (I) is solvable.

The reasoning in the footnote can be extended as follow: *if we know in advance that certain subsystem (S) of (\mathcal{S}) is solvable, we can be sure that the admissible aggregation weights λ_i which lead (\mathcal{S}) to a contradiction definitely associate positive weights with some of the inequalities outside of (S) .* Indeed, otherwise the contradictory aggregation, given by λ , of the inequalities from (\mathcal{S}) would be a contradictory aggregation of the inequalities from (S) , which is impossible, since (S) is solvable.

Corollaries of GTA

Specifying somehow the structure of (\mathcal{S}) and applying GTA, we get instructive “special cases” of GTA. Here are several most renown special cases (on a closest inspection, every one of them is equivalent to GTA)

Homogeneous Farkas Lemma is obtained from GTA when restricting (\mathcal{S}) to be a system of homogeneous inequalities ($b_i = 0$ for all i) and allowing for exactly one strict inequality in the system (check it!). Of course, with our way to derive GTA, this observation adds nothing to our body of knowledge — we used HFL to obtain GTA.

Inhomogeneous Farkas Lemma. The next statement does add much to our body of knowledge:

Theorem 3.1.2 [Inhomogeneous Farkas Lemma] *A nonstrict linear inequality*

$$a_0^T x \leq b_0 \tag{3.1.5}$$

is a consequence of a solvable system of nonstrict inequalities

$$a_i^T x \leq b_i, 1 \leq i \leq m \tag{3.1.6}$$

iff the target inequality (3.1.5) is a weighted sum, with nonnegative coefficients, of the inequalities from the system and the identically true inequality $0^T x \leq 1$, that is, iff there exist nonnegative coefficients $\lambda_1, \dots, \lambda_m$ such that

$$\sum_{i=1}^m \lambda_i a_i = a_0, \sum_{i=1}^m \lambda_i b_i \leq b_0. \tag{3.1.7}$$

²look at (II): this system in fact is not affected by the presence of strict inequalities in (\mathcal{S}) and would remain intact if we were dropping from (\mathcal{S}) all strict inequalities. Thus, if (II) were solvable, already the subsystem of nonstrict inequalities from (\mathcal{S}) would be insolvable, which is not the case.

To see the role of the identically true inequality, note that to say that there exist nonnegative $\lambda_1, \dots, \lambda_m$ satisfying (3.1.7) is exactly the same as to say that there exist nonnegative $\lambda_1, \dots, \lambda_{m+1}$ such that

$$[a_0; b_0] = \sum_{i=1}^m [\lambda_i a_i; b_i] + \lambda_{m+1} [0; \dots; 0; 1].$$

Proof. The fact that the existence of $\lambda_i \geq 0$ satisfying (3.1.7) implies that the target inequality (3.1.5) is a consequence of the system (3.1.6) is evident — look at the weighted sum $\sum_i \lambda_i a_i^T x \leq \sum_i \lambda_i b_i$ of the inequalities of the system and compare it with the target inequality; note that here the solvability of the system is irrelevant. To prove the inverse, assume that the target inequality is a consequence of the system and the system is solvable, and let us prove the existence of $\lambda_i \geq 0$ satisfying (3.1.7). Indeed, since the target inequality is a consequence of the system (3.1.6), the system of linear inequalities

$$-a^T x < -b, a_1^T x \leq b_1, \dots, a_m^T x \leq b_m \quad (*)$$

is insolvable. The GTA says that then an appropriate weighted sum, with nonnegative weights μ_0, \dots, μ_m , of the inequalities from the latter system is a contradictory inequality. It follows that μ_0 is nonzero (since otherwise the weights μ_1, \dots, μ_m were certifying that the system (3.1.6) is insolvable, which is not the case). When $\mu_0 > 0$, the fact that the weighted sum

$$\left[\mu_0 [-a_0] + \sum_{i=1}^m \mu_i a_i \right]^T x < \mu_0 [-b_0] + \sum_{i=1}^m \mu_i b_i$$

of the inequalities from (*) is contradictory reads

$$\mu_0 a_0 = \sum_{i=1}^m \mu_i a_i, \quad \mu_0 b_0 \geq \sum_{i=1}^m \mu_i b_i,$$

meaning that $\lambda_i = \mu_i / \mu_0$ are nonnegative and satisfy (3.1.7). □

We are about to present two other renown equivalent reformulations of the GTA.

Exercise 3.1 1) Prove Gordan Theorem on Alternative:

A system of strict homogeneous linear inequalities $Ax < 0$ in variables x has a solution iff the system $A^T \lambda = 0, \lambda \geq 0$ in variables λ has only trivial solution $\lambda = 0$.

2) Prove Motzkin Theorem on Alternative:

A system $Ax < 0, Bx \leq 0$ of strict and nonstrict homogeneous linear inequalities has a solution iff the system $A^T \lambda + B^T \mu = 0, \lambda \geq 0, \mu \geq 0$ in variables λ, μ has no solution with $\lambda \neq 0$.

Discussion. It is time now to explain why GTA is indeed a deep fact. Consider the following solvable system of linear inequalities:

$$-1 \leq u \leq 1, -1 \leq v \leq 1. \quad (!)$$

From this system it clearly follows that $u^2 \leq 1$, $v^2 \leq 1$, whence $u^2 + v^2 \leq 2$. Applying the Cauchy inequality, we have

$$u_1 + u_2 = 1 \cdot u + 1 \cdot v \leq \sqrt{1^2 + 1^2} \sqrt{u^2 + v^2} = \sqrt{2} \sqrt{u^2 + v^2}$$

which combines with the already proved $u^2 + v^2 \leq 2$ to imply that $u + v \leq \sqrt{2} \sqrt{2} = 2$. Thus, the linear inequality $u + v \leq 2$ is a consequence of the solvable system of linear inequalities (!). GTA says that we could get the same target inequality by a very simple process, free of taking squares and Cauchy inequality — merely by taking an admissible weighted sum of the inequalities from the original system. In our toy example, this is evident: we should just sum up the inequalities $u \leq 1$ and $v \leq 1$ from the system. However, a derivation of the outlined type could take 1,000 highly nontrivial (and “highly nonlinear”) steps; a statement, like GTA, capable to predict in advance that a chain, whatever sophisticated, of derivations of this type which starts with a solvable system of linear inequalities and ends with a linear inequality, can be replaced with just taking weighted sum, with nonnegative coefficients, of the inequalities from the original system, should indeed be deep...

It should be added that in both Homogeneous and Inhomogeneous Farkas Lemma, it is crucial that we speak about linear inequalities. Consider, for example, a target homogeneous quadratic inequality

$$x^T A_0 x \leq 0 \quad (*)$$

along with a system

$$x^T A_i x \leq 0, \quad 1 \leq i \leq m, \quad (!)$$

of similar inequalities, and let us ask ourselves when the target inequality is a consequence of the system. A straightforward attempt to extend HFL to quadratic case would imply the conjecture “(*) is a consequence of (!) is and only if the symmetric matrix A_0 is a conic combination of the matrices A_i , $i = 1, \dots, m$.” On a closest inspection, we realize that to expect the validity of this conjecture would be too much, since there exist nontrivial (i.e., with nonzero symmetric matrix A_0) *identically true* homogeneous quadratic inequalities $x^T A_0 x \leq 0$, e.g., $-x^T x \leq 0$; these are inequalities produced by the so called *negative semidefinite* symmetric matrices. Clearly, such an inequality is a consequence of an empty system (!) (or a system where all the matrices A_1, \dots, A_k are zero), while the matrix A_0 in question definitely is not a conic combination of an empty collection of matrices, or a collection comprised of zero matrices. Well, if there exist identically true homogeneous quadratic inequalities, why not to think about them as about additional inequalities participating in (!)? Such a viewpoint leads us to an improved conjecture “a homogeneous quadratic inequality (*) is a consequence of a finite system (!) of similar inequalities if and only if A_0 can be represented as a conic combination of A_1, \dots, A_m *plus a negative semidefinite matrix*?” (Note that in the case of homogeneous linear inequalities similar correction of HFL “is empty”, since the only homogeneous *identically true* linear inequality is trivial — all the coefficients are zero). Unfortunately, the corrected conjecture fails to be true in general; its “if” part “if A_0 is a conic combination of matrices A_1, \dots, A_m plus a negative semidefinite matrix” is trivially true, but the “only if” part fails to be true. Were it not so, there would be no difficult optimization problems at all (e.g., P would be equal to NP), but we are not that lucky... This being said, it should be noted that

- already the trivially true “if” part of the (improved) conjecture is extremely useful — it underlies what is called *semidefinite relaxations* of difficult combinatorial problems;

- there is a special case when the improved conjecture indeed is true — this is the case when $m = 1$ and the “system” (in fact, just a single inequality) (!) is strictly feasible — there exists \bar{x}

such that $\bar{x}^T A_1 \bar{x} < 0$. The fact that in the special case in question the improved conjecture is true is called \mathcal{S} -Lemma which reads

Let A, B be symmetric matrices of the same size. A homogeneous quadratic inequality $x^T A_0 x \leq 0$ is a consequence of strictly feasible homogeneous quadratic inequality $x^T A_1 x \leq 0$ iff there exists $\lambda \geq 0$ such that the matrix $A_0 - \lambda A_1$ is negative semidefinite.

Whatever poor looks this fact as compared to its “linear analogy” HFL, \mathcal{S} -lemma is one of the most useful facts of Optimization.

3.1.2 Answering Questions

Now we are in a good position to answer question we posed in the preface of the lecture. All these questions were on how to certify such and such property; to save words when presenting answers, let us start with setting up some terminology. Imagine that we are interested in certain property of an object and know how to certify this property, that is, we have in our disposal a family of candidate certificates and an easy-to-verify condition \mathcal{C} on a pair (“object,” “candidate certificate”) such that whenever a candidate certificate and the object under consideration fit the condition \mathcal{C} , the object does possess the property of interest. In this situation we shall say that we have in our disposal a *certification scheme* for the property.

E.g., let the objects to be considered be polyhedral sets in \mathbf{R}^n , given by their descriptions of the form $\{Ax \leq b\}$, the property of interest be the nonemptiness of a set, candidate certificates be vectors from \mathbf{R}^n , and the condition \mathcal{C} be “a candidate certificate \bar{x} satisfies the system of constraints $Ax \leq b$ specifying the object under consideration.” What we have described clearly is a certification scheme.

By definition of a certification scheme, whenever it allows to certify that a given object X possesses the property of interest (that is, whenever there exists a candidate certificate S which makes $\mathcal{C}(X, S)$ valid), X indeed possesses the property. We say that a certification scheme is *complete*, if the inverse also is true: whenever an object possesses the property of interest, this fact can be certified by the certification scheme. For example, the outlined certification scheme for nonemptiness of a polyhedral set clearly is complete. When strengthening the condition \mathcal{C} underlying this scheme to “a candidate certificate \bar{x} has zero first coordinate and satisfies the system of constraints $Ax \leq b$ specifying the object under consideration,” we still have a certification scheme, but this scheme clearly is incomplete.

Finally, we note that certifying the presence of a property and certifying the *absence* of this property are, in general, two completely different tasks, this is why in the sequel we should (and will) consider both how to certify a property and how to certify its absence.³

When a polyhedral set is empty/nonempty? Here are the answers:

Corollary 3.1.1 *A polyhedral set $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ is nonempty iff there exists x such that $Ax \leq b$. The set is empty iff there exists $\lambda \geq 0$ such that $A^T \lambda = 0$ and $b^T \lambda < 0$.*

³Of course, if certain property admits a complete certification scheme \mathcal{S} , the absence of this property in an object X is fully characterized by saying that X does *not* admit a certificate required by \mathcal{S} ; this, however, is a negative statement, and not a certification scheme!

Indeed, the first part is a plain tautology. The second part is verified as follows: by GTA, X is empty iff there exists a weighted sum $\lambda^T Ax \leq \lambda^T b$ of the inequalities, the weights being nonnegative, which is a contradictory inequality; the latter clearly is the case iff $A^T \lambda = 0$ and $b^T \lambda < 0$. \square

When a polyhedral set contains another polyhedral set? The answer is given by

Corollary 3.1.2 *A polyhedral set $Y = \{x : p_i^T x \leq q_i, 1 \leq i \leq k\}$ contains a nonempty polyhedral set $X = \{x : A^T x \leq b\}$ iff for every $i \leq k$ there exist $\lambda^i \geq 0$ such that $p_i = A^T \lambda^i$ and $q_i \geq b^T \lambda^i$.*

Indeed, Y contains X iff every inequality $p_i^T x \leq q_i$ defining Y is satisfied everywhere on X , that is, this inequality is a consequence of the system of inequalities $Ax \leq b$; it remains to use the Inhomogeneous Farkas Lemma. \square

Now, $Y = \{x : p_i^T x \leq q_i, 1 \leq i \leq k\}$ contains $X = \{x : Ax \leq b\}$ iff either $X = \emptyset$, or $X \neq \emptyset$ and $X \subset Y$. It follows that in order to certify the inclusion $X \subset Y$, it suffices to point out either a vector λ satisfying $\lambda \geq 0, A^T \lambda = 0, b^T \lambda < 0$, thus certifying that $X = \emptyset$ (Corollary 3.1.1), or to certify that $X \neq \emptyset$ and point out a collection of vectors λ^i , satisfying $\lambda^i \geq 0, p_i = A^T \lambda^i, q_i \geq b^T \lambda^i, 1 \leq i \leq k$, thus certifying that every one of the inequalities defining Y is valid everywhere on X . In fact, in the second case one should not bother to certify that $X \neq \emptyset$, since the existence of λ^i as in Corollary 3.1.2 is *sufficient* for the validity of the inclusion $X \subset Y$ independently of whether X is or is not empty (why?). It should be added that

- the outlined certification scheme for the inclusion $X \subset Y$ is complete;
- it is trivial to certify that X is *not* contained in Y ; to this end it suffices to point out an $x \in X$ which violates one or more of the linear inequalities defining Y ; this certification scheme also is complete.

As a direct consequence of our results, we get a complete certification scheme for checking whether two polyhedral sets $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ and $Y = \{x \in \mathbf{R}^n : Cx \leq d\}$ are/are not identical. Indeed, $X = Y$ iff either both sets are empty, or both are nonempty and both the inclusions $X \subset Y$ and $Y \subset X$ hold true, and we already know how to certify the presence/absence of all properties we have just mentioned.⁴

When a polyhedral set is bounded/unbounded? *Certifying boundedness.* A polyhedral set $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ is bounded iff there exists R such that X is contained in the box $B_R = \{x \in \mathbf{R}^n : e_i^T x \leq R, -e_i^T x \leq R, 1 \leq i \leq n\}$, where e_1, \dots, e_n are the standard basic orths. Thus, certificate of boundedness is given by a real R augmented by a certificate that $X \subset B_R$. Invoking the previous item, we arrive at the following “branching” scheme: we either certify that X is empty, a certificate being a vector λ satisfying $\lambda \geq 0, A^T \lambda = 0, b^T \lambda < 0$, or point

⁴At a first glance, the very question to which we have answered seems to be fully scholastic; in comparison, even the question “how many angels can sit at the tip of a needle” discussed intensively by the Medieval scholars seems to be practical. In fact the question is very deep, and the possibility to answer it affirmatively (that is, by indicating a complete certification scheme where the validity of candidate certificates can be efficiently verified) is “an extremely rare commodity.” Indeed, recall that we want to certify that two sets are/are not identical looking at the *descriptions* of these sets, and not at these sets as abstract mathematical beasts in the spirit of Plato. To illustrate the point, the Fermat Theorem just asks whether the set of positive integer quadruples x, y, z, p satisfying $x^p + y^p - z^p = 0$ and $p \geq 3$ is or is not equal to the set of positive integer quadruples (x, y, z, p) satisfying $x = 0$; this form of the theorem does not make it neither a trivial, nor a scholastic statement.

out a collection $(R, \lambda^1, \mu^1, \dots, \lambda^n, \mu^n)$ satisfying $\lambda^i \geq 0, A^T \lambda^i = e_i, b^T \lambda^i \leq R, \mu^i \geq 0, A^T \mu^i = -e_i, b^T \mu^i \leq R, 1 \leq i \leq m$, thus certifying that $X \subset B_R$. The resulting certification scheme is complete (why?).

Certifying unboundedness. An unbounded set clearly should be nonempty. By Corollary 2.4.5, a polyhedral set is unbounded iff its recessive cone is nontrivial. Applying Proposition 2.3.4, we conclude that in order to certify unboundedness of a polyhedral set $X = \{x \in \mathbf{R}^n : Ax \leq b\}$, it suffices to point out a vector \bar{x} such that $A\bar{x} \leq b$ and a *nonzero* vector y such that $Ay \leq 0$, and this certification scheme is complete.

A useful corollary of the results in this item is that the properties of a *nonempty* polyhedral set $X = \{x : Ax \leq b\}$ to be bounded/unbounded are independent of a particular value of b , *provided that with this value of b , the set X is nonempty.*

How to certify that the dimension of a polyhedral set $X = \{x \in \mathbf{R}^n : Ax \leq b\}$ is \geq / \leq a given d ? First of all, only nonempty sets possess well defined dimension, so that the “zero step” is to certify that the set in question is nonempty. We know how to certify both this property and its absence; thus, we can work under the assumption that the nonemptiness of X is already certified.

Let us start with certifying the fact that $\dim X \geq d$, where d is a given integer. By Theorem 2.1.2.(iii) and Lemma 2.1.1, $\dim X = \dim \text{Aff}(X) \geq d$ iff one can point out $d + 1$ vectors $x_0, \dots, x_d \in X$ such that the d vectors $x_1 - x_0, x_2 - x_0, \dots, x_d - x_0$ are linearly independent. Both the inclusions $x_i \in X, i = 0, 1, \dots, d$, and the linear independence of $x_1 - x_0, \dots, x_d - x_0$ is easy to verify (how?), so that we can think of a collection x_0, \dots, x_d with the outlined properties as a certificate for the relation $\dim X \geq d$. The resulting certification scheme clearly is complete.

Now let us think how to certify the relation $\dim X \leq d$, d being a given integer. There is nothing to certify if $d \geq n$, so that we can assume that $d < n$. For a nonempty $X \subset \mathbf{R}^n$, the relation $\dim X \leq d$ holds iff there exists an affine subspace M in \mathbf{R}^n such that $X \subset M$ and $\dim M \leq d$; the latter means *exactly* that there exists a system of $n - d$ linear equations $a_i^T x = b_i$ with linearly independent a_1, \dots, a_{n-d} such that M is contained in the solution set of the system (see section 2.1.2). The intermediate summary is that $\dim X \leq d$ iff there exist $n - d$ pairs (a_i, b_i) with linearly independent a_1, \dots, a_{n-d} such that for every i $a_i^T x \equiv b_i$ on X , or, which is the same, both $a_i^T x \leq b_i$ and $-a_i^T x \leq -b_i$ everywhere on X . Recalling how to certify that a linear inequality $\alpha^T x \leq \beta$ is a consequence of the solvable system $Ax \leq b$ of linear inequalities defining X , we arrive at the following conclusion: In order to certify that $\dim X \leq d$, where $X = \{x \in \mathbf{R}^n : A^T x \leq b\}$, A being an $m \times n$ matrix, and X is nonempty, it suffices to point out $n - d$ vectors $a_i \in \mathbf{R}^n$, $n - d$ reals b_i and $2(n - d)$ vectors $\lambda^i, \mu^i \in \mathbf{R}^m$ such that

- a_1, \dots, a_{n-d} are linearly independent,
- for every $i \leq n - d$, one has $\lambda^i \geq 0, A^T \lambda^i = a_i$ and $b^T \lambda^i \leq b_i$,
- for every $i \leq n - d$, one has $\mu^i \geq 0, A^T \mu^i = -a_i, b^T \mu^i \leq -b_i$.

Every one of the above conditions is easy to verify, so that we have defined a certification scheme for the relation $\dim X \leq m$, and this scheme clearly is complete.

3.1.3 Certificates in Linear Optimization

Consider an LO program in the form

$$\text{Opt} = \max_x \left\{ c^T x : \begin{cases} Px \leq p & (\ell) \\ Qx \geq q & (g) \\ Rx = r & (e) \end{cases} \right\} \quad (3.1.8)$$

("ℓ" from "less or equal", "g" from "greater or equal", "e" from "equal").

Of course, we could stick to a "uniform" format where all the constraints are, say, the " \leq "-inequalities; we prefer, however, to work with a more flexible format, reflecting how the LO's look "in reality." Our goal is to show how to certify the basic properties of an LO program.

Certifying feasibility/infeasibility

Certificate for feasibility of (3.1.8) is, of course, a feasible solution to the problem. Certificate for infeasibility is, according to our theory, a collection of aggregation weights $\lambda = [\lambda_\ell; \lambda_g; \lambda_e]$ associated with the constraints of the program (so that $\dim \lambda_\ell = \dim p$, $\dim \lambda_g = \dim q$, $\dim \lambda_e = \dim r$ such that first, it is legitimate to take the weighted sum of the constraints, and, second, the result of aggregation is a contradictory inequality. The restriction to be legitimate amounts to

$$\lambda_\ell \geq 0, \lambda_g \leq 0, \text{ no restrictions on } \lambda_e;$$

when aggregation weights λ satisfy these restrictions, the weighted by λ sum of the constraints is the inequality

$$[P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r]^T x \leq p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e,$$

and this inequality is contradictory if and only if the vector of coefficients of x in the left hand side vanishes, and the right hand side is negative. Thus, λ certifies infeasibility iff

$$\lambda_\ell \geq 0, \lambda_g \leq 0, P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r = 0, p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e < 0. \quad (3.1.9)$$

According to our theory, the outlined certification schemes for feasibility and for infeasibility are complete.

Certifying boundedness/unboundedness

Certifying boundedness of (3.1.8). An LO program (3.1.8) is bounded iff it is either infeasible, or it is feasible and the objective is bounded below on the feasible set, that is, there exists a real μ such that the inequality $c^T x \leq \mu$ is a consequence of the constraints. We already know how to certify infeasibility; to certify boundedness for a feasible problem, we should certify feasibility (which we again know how to do) and to certify that the inequality $c^T x \leq \mu$ is a consequence of a *feasible* system of constraints, which, by the principle expressed by the Inhomogeneous Farkas Lemma, amounts to pointing out a collection of weights $\lambda = [\lambda_\ell; \lambda_g; \lambda_e]$ which makes it legitimate to take the weighted sum of the constraints and is such that this weighted sum is of the form $c^T x \leq \text{constant}$. Thus, λ in question should satisfy

$$\lambda_\ell \geq 0, \lambda_g \leq 0, P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r = c. \quad (3.1.10)$$

The resulting certification scheme for boundedness — "either certify infeasibility according to (3.1.9), or point out a certificate for feasibility and a λ satisfying (3.1.10)" — is complete. On a

closest inspection, there is no need to bother about certifying feasibility in the second “branch” of the scheme, since pointing out a λ satisfying (3.1.10) certifies boundedness of the program independently of whether the program is or is not feasible (why?)

As an important consequence, we get the following

Corollary 3.1.3 *For an LO program $\max_x \{c^T x : P^T x \leq p, Q^T x \geq q, R^T x = r\}$ the property to be or not to be bounded is independent of the value of the right hand side vector $b = [p; q; r]$, provided that with this b the problem is feasible.*

Indeed, by completeness of our certification scheme for boundedness, a *feasible* LO program is bounded iff and only if there exists λ satisfying (3.1.10), and the latter fact is or is not valid independently of what is the value of b . \square

Note that Corollary 3.1.3 “mirrors” the evident fact that the property of an LO program to be or not to be feasible is independent of what is the objective.

Certifying unboundedness of (3.1.8). Program (3.1.8) is *unbounded* iff it is feasible and the objective is not bounded above on the feasible set. By Corollary 2.4.4, the objective of a feasible LO is unbounded from above on the feasible set iff this set has a recessive direction y along which the objective grows: $c^T y > 0$. It follows that a certificate for unboundedness can be specified as a pair x, y such that

$$\begin{aligned} (a) \quad & Px \leq p, Qx \geq 0, Rx = r \\ (b) \quad & Py \leq 0, Qy \geq 0, Ry = 0 \\ (c) \quad & c^T y > 0 \end{aligned} \tag{3.1.11}$$

Here (a) certifies the fact that the program is feasible, and (b) expresses equivalently the fact that y is a recessive direction of the feasible set (cf. Proposition 2.3.4). The resulting certification scheme is complete (why?).

Certifying solvability/insolvability

An LO program (3.1.8) is solvable iff it is feasible and above bounded (Corollary 2.4.7), and we already have in our disposal complete certification schemes for both these properties.

Similarly, (3.1.8) is insolvable iff it is either infeasible, or is feasible and is (above) unbounded, and we already have in our disposal complete certification schemes for both these properties.

Certifying optimality/nonoptimality

A candidate solution \bar{x} to (3.1.8) is optimal if and only if it is feasible and the linear inequality $c^T x \leq c^T \bar{x}$ is a consequence of the (feasible!) system of constraints in (3.1.8). Invoking Inhomogeneous Farkas Lemma, we conclude that a certificate for optimality of \bar{x} can be obtained by augmenting \bar{x} by a $\lambda = [\lambda_\ell; \lambda_g; \lambda_e]$ satisfying the relations

$$\begin{aligned} (a) \quad & \lambda_\ell \geq 0, \lambda_g \leq 0, \\ (b) \quad & P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r = c \\ (c) \quad & p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_r \leq c^T \bar{x}. \end{aligned} \tag{3.1.12}$$

and that the resulting certification scheme for optimality of \bar{x} is complete *provided that \bar{x} is feasible*.

Observe that for whatever λ satisfying (3.1.12.a) we have

$$\lambda_\ell^T P\bar{x} \leq p^T \lambda_\ell, \lambda_g^T Q\bar{x} \leq q^T \lambda_g, \lambda_e^T R\bar{x} = r^T \lambda_e, \quad (*)$$

and the first two inequalities can be equalities iff the entries in λ_ℓ and λ_g corresponding to the *nonactive* at \bar{x} inequality constraints – those which are satisfied at \bar{x} as strict inequalities – should be zeros. Summing up the inequalities in (*), we end up with

$$\lambda_\ell^T P\bar{x} + \lambda_g^T Q\bar{x} \leq q^T \lambda_g + \lambda_e^T R\bar{x} \leq p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_r. \quad (!)$$

On the other hand, if λ satisfies (3.1.12.c), then the inequality opposite to (!) takes place, which is possible iff the inequalities in (*) are equalities, which, as we have seen, is equivalent to the fact that the entries in λ associated with *nonactive* at \bar{x} inequality constraints are zero. Vice versa, when the entries in λ satisfying the *nonactive* at \bar{x} inequality constraints are zero, then (3.1.12.c) is satisfied as an equality as well. The bottom line is that λ satisfies (3.1.12) iff λ satisfies the first two relations in (3.1.12) and, in addition, the entries in λ associated with *non-active* at \bar{x} inequality constraints of (3.1.8) are zeros. We have arrived at the following

Proposition 3.1.2 [Karush-Kuhn-Tucker Optimality Conditions in LO] *A feasible solution \bar{x} to an LO program (3.1.8) is optimal for the program iff \bar{x} can be augmented by Lagrange multipliers $\lambda = [\lambda_\ell; \lambda_g; \lambda_e]$ in such a way that the following two facts take place:*

- *multipliers corresponding to the " \leq "-inequality constraints (3.1.8.ℓ) are nonnegative, multipliers corresponding to the " \geq "-inequality constraints (3.1.8.g) are nonpositive, and, in addition, multipliers corresponding to the *nonactive* at x inequality constraints are zero (all this is called “complementary slackness”);*

- *one has*

$$c = P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r.$$

We have seen how to certify that a feasible candidate solution to (3.1.8) is optimal for the program. As about certifying nonoptimality, this is immediate: \bar{x} is not optimal iff it either is not feasible for the program, or there exists a feasible solution y with $c^T y > c^T \bar{x}$, and such an y certifies the nonoptimality of \bar{x} . The resulting “two-branch” certification scheme clearly is complete.

A corollary: faces of a polyhedral set revisited

Recall that a face of a polyhedral set $X = \{x \in \mathbf{R}^n : a_i^T x \leq b_i, 1 \leq i \leq m\}$ is a *nonempty* subset of X which is cut off X by converting some of the inequalities $a_i^T x \leq b_i$ into equalities $a_i^T x = b_i$. Thus, every face of X is of the form $X_I = \{x : a_i^T x \leq b_i, i \notin I, a_i^T x = b_i, i \in I\}$, where I is certain subset of the index set $\{1, \dots, m\}$ (which should be such that $X_I \neq \emptyset$). As we have already mentioned, a shortcoming of this definition is that it is not geometric — it is expressed in terms of a particular representation of X rather than in terms of X as a set. Now we are in a position to eliminate this drawback.

Proposition 3.1.3 *Let $X = \{x \in \mathbf{R}^n : a_i^T x \leq b_i, 1 \leq i \leq m\}$, be a nonempty polyhedral set.*

(i) *If $c^T x$ is a linear form which is bounded from above on X (and thus attains its maximum on X), then the set $\text{Argmax}_X c^T x$ of maximizers of the form is a face of X .*

(ii) *Vice versa, every face X_I of X can be represented in the form $X_I = \text{Argmax}_X c^T x$ for appropriately chosen linear form $c^T x$.*

In particular, every vertex of X is the unique maximizer, taken over $x \in X$, of an appropriately chosen linear form.

Since the sets of the form $\text{Argmax}_{x \in X} c^T x$ are defined in terms of X as a set, with no reference to a particular representation of X , Proposition indeed provides us with a purely geometric characterization of the faces.

Proof of Proposition 3.1.3 is easy. To verify (i), let \bar{x} be a maximizer of $c^T x$ over X , and let J be the set of indices of all constraints $a_i^T x \leq b_i$ which are active at \bar{x} : $J = \{i : a_i^T \bar{x} = b_i\}$. Invoking the “only if” part of Proposition 3.1.2 and noting that we are in the situation of $P^T = [a_1; \dots; a_m]$ with Q and R being empty, we conclude that there exist *nonnegative* λ_i , $i \in J$, such that $c = \sum_{i \in J} \lambda_i a_i$. Let us set $I = \{i \in J : \lambda_i > 0\}$, so that in fact $c = \sum_{i \in I} \lambda_i a_i$, and let us verify that $\text{Argmax}_X c^T x = X_I$ (so that $\text{Argmax}_X c^T x$ is a face in X , as claimed). If I is empty, then $c = \sum_{i \in I} \lambda_i a_i = 0$, so that $\text{Argmax}_X c^T x = X_\emptyset = X_I$, as required. Now let $I \neq \emptyset$. We have

$$\begin{aligned} \forall x \in X : c^T x &= [\sum_{i \in I} \lambda_i a_i]^T x = \sum_{i \in I} \lambda_i [a_i^T x] \underbrace{\leq}_{(*)} \sum_{i \in I} \lambda_i b_i \\ \max_{x \in X} c^T x &= c^T \bar{x} = \sum_{i \in I} [\lambda_i a_i^T \bar{x}] = \sum_{i \in I} \lambda_i b_i. \end{aligned}$$

(we have taken into account that $\lambda_i > 0$). From these relations it is clear that $x \in X$ is a maximizer of the linear form given by c iff the inequality $(*)$ is an equality; the latter, for $x \in X$, takes place iff $a_i^T x = b_i$ for all $i \in I$ (since for such an x , $a_i^T x \leq b_i$ and λ_i are strictly positive, $i \in I$), that is, iff $x \in X_I$, as required. (i) is proved.

To prove (ii), consider a face X_I , and let us prove that it is nothing but $\text{Argmax}_X c^T x$ for a properly chosen c . There is nothing to prove when $I = \emptyset$, so that $X_I = X$; in this case we can take $c = 0$. Now let I be nonempty, let us choose whatever strictly positive λ_i , $i \in I$, and set $c = \sum_{i \in I} \lambda_i a_i$. By the “if” part of Proposition 3.1.2, every point of the (nonempty!) face X_I of X is a maximizer of $c^T x$ over $x \in X$, and since all λ_i , $i \in I$, are strictly positive, the reasoning used to prove (i) shows that vice versa, every maximizer of $c^T x$ over X belongs to X_I . Thus, $X_I = \text{Argmax}_X c^T x$ for the c we have built. \square

3.2 LO Duality

We are about to develop the crucial concept of the *dual* to an LO program. The related constructions and results mostly are already known to us, so that this section is a kind of “intermediate summary.”

3.2.1 The Dual of an LO Program

Consider an LO program in the form of (3.1.8) (we reproduce the formulation for reader’s convenience):

$$\text{Opt}(P) = \max_x \left\{ c^T x : \begin{cases} Px \leq p & (\ell) \\ Qx \geq q & (g) \\ Rx = r & (e) \end{cases} \right\}; \quad (P)$$

From now on we refer to this problem as the *primal* one. The origin of the problem *dual* to (P) stems from the desire to find a systematic way to bound from above the optimal value of

(P). The approach we intend to use is already well known to us — this is aggregation of the constraints. Specifically, let us associate with the constraints of (P) the vector of *dual variables* (called also *Lagrange multipliers*) $\lambda = [\lambda_\ell; \lambda_g; \lambda_e]$ restricted to satisfy sign constraints

$$\lambda_\ell \geq 0; \lambda_g \leq 0. \quad (3.2.1)$$

Using such a λ as the vector of aggregation weights for the constraints of (P), we get the scalar inequality

$$[P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r]^T x \leq p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e \quad (*)$$

which, by its origin, is a consequence of the system of constraints of (P). Now, if we are lucky to get in the left hand side our objective, that is, if

$$P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r = c,$$

then (*) says to us that $p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e$ is an upper bound on $\text{Opt}(P)$. The dual problem asks us to build the best possible — the smallest — bound of this type. Thus, the dual problem reads

$$\text{Opt}(D) = \min_{\lambda=[\lambda_\ell; \lambda_g; \lambda_e]} \left\{ d^T \lambda := p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e : \begin{cases} \lambda_\ell \geq 0 \\ \lambda_g \leq 0 \\ P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r = c \end{cases} \right\}. \quad (D)$$

This is again an LO program.

3.2.2 Linear Programming Duality Theorem

The most important relations between the primal and the dual LO problems are presented in the following

Theorem 3.2.1 [Linear Programming Duality Theorem] *Consider primal LO program (P) along with its dual (D). Then*

(i) [Symmetry] *Duality is symmetric: (D) is an LO program, and its dual is (equivalent to) (P).*

(ii) [Weak duality] $\text{Opt}(D) \geq \text{Opt}(P)$, or, equivalently, for every pair (x, λ) of feasible solutions to (P) and (D) one has

$$\text{DualityGap}(x, \lambda) := d^T \lambda - c^T x = [p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e] - c^T x \geq 0.$$

(iii) [Strong duality] *The following properties are equivalent to each other:*

(iii.1) (P) is feasible and bounded from above

(iii.2) (P) is solvable

(iii.3) (D) is feasible and bounded from below

(iii.4) (D) is solvable

(iii.5) Both (P) and (D) are feasible

and whenever one of these equivalent to each other properties takes place, we have $\text{Opt}(P) = \text{Opt}(D)$.

Proof. (i): In order to apply the recipe for building the dual to (D) , we should first write it down as a maximization problem in the format of (P) , that is, as

$$-\text{Opt}(D) = \max_{\lambda=[\lambda_\ell; \lambda_g; \lambda_e]} \left\{ -[p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e] : \begin{cases} \lambda_g \leq 0 & (\ell) \\ \lambda_\ell \geq 0 & (g) \\ P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r = c & (e) \end{cases} \right\}.$$

This is the problem in the form of (P) , with the matrices $[0, I, 0]$, $[I, 0, 0]$, $[P^T, Q^T, R^T]$ in the role of P , Q , R , respectively; here I and 0 stand for the unit and the zero matrices of appropriate sizes (not necessary the same in different places). Applying to the latter problem the recipe for building the dual, we arrive at the LO program

$$\min_{y=[y_\ell; y_g; y_r]} \left\{ 0^T y_\ell + 0^T y_g + c^T y_r : \begin{cases} y_\ell \geq 0 \\ y_g \leq 0 \\ [y_g + P y_r; y_\ell + Q y_r; R y_r] = [-p; -q; -r] \end{cases} \right\}.$$

We can immediately eliminate the variables y_ℓ and y_g . Indeed, y_ℓ does not affect the objective, and what the constraints want of y_ℓ is $y_\ell \geq 0$, $y_\ell + Q y_r = -q$, which amounts to $-Q y_r \geq q$. The situation with y_g is similar. Eliminating y_ℓ and y_g , we arrive at the following equivalent reformulation of the problem dual to (D) :

$$\min_{y_r} \left\{ c^T y_r : \begin{cases} P y_r \geq -p \\ Q y_r \leq -q \\ R y_r = -r \end{cases} \right\},$$

which is nothing but (P) (set $x = -y_r$). (i) is proved.

(ii): Weak duality is readily given by the construction of (D) .

(iii): Let us first verify that all five properties (iii.1) – (iii.5) are equivalent to each other.

(iii.1) \Leftrightarrow (iii.2): a solvable LO program clearly is feasible and bounded, the inverse is true due to Corollary 2.4.7.(i).

(iii.3) \Leftrightarrow (iii.4): follows from the already proved equivalence (iii.1) \Leftrightarrow (iii.2) due to the fact that the duality is symmetric.

(iii.2) \Rightarrow (iii.5): If (P) is solvable, (P) is feasible. In order to verify that (D) is feasible as well, note that the inequality $c^T x \leq \text{Opt}(P)$ is a consequence of the system of the constraints in (P) , and this system is feasible; applying the Inhomogeneous Farkas Lemma, the inequality $c^T x \leq \text{Opt}(P)$ can be obtained by taking admissible weighted sum of the constraints of (P) and the identically true inequality $0^T x \leq 1$, that is, there exists $\lambda_0 \geq 0$ and $\lambda = [\lambda_\ell; \lambda_g; \lambda_e]$ satisfying the sign constraints (3.2.1) such that the aggregated inequality

$$\lambda_0 [0^T x] + \lambda_\ell^T P x + \lambda_g^T Q x + \lambda_e^T R x \leq \lambda_0 \cdot 1 + \lambda_\ell^T p + \lambda_g^T q + \lambda_e^T r$$

is exactly the inequality $c^T x \leq \text{Opt}(P)$, meaning that

$$P^T \lambda_\ell + q^T \lambda_g + R^T \lambda_e = c$$

and

$$\lambda_\ell^T p + \lambda_g^T q + \lambda_e^T r = \text{Opt}(P) - \lambda_0. \quad (*)$$

Since λ satisfies the sign constraints from (D) , we conclude that λ is feasible for (D) , so that D is feasible, as claimed. As a byproduct, we see from $(*)$ that the dual objective at λ is $\leq \text{Opt}(P)$

(since $\lambda_0 \geq 0$), so that $\text{Opt}(D) \leq \text{Opt}(P)$. The strict inequality is impossible by Weak duality, and thus $\text{Opt}(P) = \text{Opt}(D)$.

(iii.4) \Rightarrow (iii.5): this is the same as the previous implication due to the fact that the duality is symmetric.

(iii.5) \Rightarrow (iii.1): in the case of (iii.5), (P) is feasible; since (D) is feasible as well, (P) is bounded by Weak duality, and thus (iii.1) takes place.

(iii.5) \Rightarrow (iii.3): this is the same as the previous implication due to the fact that the duality is symmetric.

We have proved that (iii.1) \Leftrightarrow (iii.2) \Rightarrow (iii.5) \Rightarrow (iii.1), and that (iii.3) \Leftrightarrow (iii.4) \Rightarrow (iii.5) \Rightarrow (iii.3). Thus, all 5 properties are equivalent to each other. We have also seen that (iii.2) implies that $\text{Opt}(P) = \text{Opt}(D)$. \square

3.3 Immediate Applications of Duality

In this section, we outline several important applications of the LO Duality Theorem.

3.3.1 Optimality Conditions in LO

The following statement (which is just a reformulation of Proposition 3.1.2) is the standard formulation of optimality conditions in LO:

Proposition 3.3.1 [Optimality conditions in LO] *Consider the primal-dual pair of problems (P) , (D) and assume that both of them are feasible. A pair (x, λ) of feasible solutions to (P) and to (D) is comprised of optimal solutions to the respective problems*

— [Zero Duality Gap] *iff the duality gap, as evaluated at this pair, is 0:*

$$\text{DualityGap}(x, \lambda) := [p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_e] - c^T x = 0$$

as well as

— [Complementary Slackness] *iff all the products of Lagrange multipliers λ_i associated with the inequality constraints of (P) and the residuals in these constraints, as evaluated at x , are zeros:*

$$[\lambda_\ell]_i [Px - p]_i = 0 \forall i, \quad [\lambda_g]_j [Qx - q]_j = 0 \forall j.$$

Proof. (i): Under the premise of Proposition we have $\text{Opt}(P) = \text{Opt}(D)$ by the LP Duality Theorem, meaning that

$$\text{DualityGap}(x, \lambda) = [p^T \lambda_\ell + q^T \lambda_g + r^T \lambda_r] - \text{Opt}(D)] + [\text{Opt}(P) - c^T x].$$

Since x, λ are feasible for the respective problems, the quantities in brackets are nonnegative, so that the duality gap can be zero iff both these quantities are zeros; the latter is the same as to say that x is primal-, and λ is dual optimal.

(ii): This is the same as (i) due to the following useful observation:

Whenever x is primal-, and λ is dual feasible, we have

$$\text{DualityGap}(x, \lambda) = \lambda_\ell^T (p - Px) + \lambda_g^T (q - Qx). \quad (3.3.1)$$

Indeed,

$$\begin{aligned}
\text{DualityGap}(x, \lambda) &= \lambda_\ell^T p + \lambda_g^T q + \lambda_r^T r - c^T x \\
&= \lambda_\ell^T p + \lambda_g^T q + \lambda_r^T r - [P^T \lambda_\ell + Q^T \lambda_g + R^T \lambda_r]^T x \text{ [since } \lambda \text{ is dual feasible]} \\
&= \lambda_\ell^T (p - Px) + \lambda_g^T (q - Qx) + \lambda_r^T [r - Rx] \\
&= \lambda_\ell^T (p - Px) + \lambda_g^T (q - Qx) \text{ [since } x \text{ is primal feasible]}
\end{aligned}$$

It remains to note that the right hand side in (3.3.1) is

$$\sum_i [\lambda_\ell]_i [P - Px]_i + \sum_j [\lambda_g]^T [q - Qx]_j, \quad (!)$$

and all terms in these two sums are nonnegative due to sign restrictions on λ coming from (D) and the fact that x is primal feasible. Thus, $\text{DualityGap}(x, \lambda)$ is zero iff all terms in (!) are zeros, as claimed. \square

3.3.2 Geometry of a Primal-Dual Pair of LO programs

Consider an LO program

$$\text{Opt}(P) = \max_x \{c^T x : Px \leq p, Rx = r\} \quad (P)$$

along with its dual program

$$\text{Opt}(D) = \min_{\lambda=[\lambda_\ell; \lambda_e]} \{p^T \lambda_\ell + r^T \lambda_e : \lambda_\ell \geq 0, P^T \lambda_\ell + R^T \lambda_e = c\} \quad (D)$$

Note that to save notation (and of course w.l.o.g.) we have assumed that all the inequalities in the primal problem are " \leq ".

Our goal here is to rewrite both the problems in a "purely geometric" form, which, as we shall see, reveals a beautiful, simple and instructive geometry of the pair.

First, assume that the systems of linear equations participating in (P) and in (D) are solvable, and let \bar{x} , $-\bar{\lambda} = -[\bar{\lambda}_\ell; \bar{\lambda}_e]$ be solutions to the respective systems:

$$\begin{aligned}
(a) \quad & R\bar{x} = r; \\
(b) \quad & P^T \bar{\lambda}_\ell + R^T \bar{\lambda}_e = -c.
\end{aligned} \quad (3.3.2)$$

Note that the assumption of solvability we have made is much weaker than feasibility of (P) and (D), since at this point we do not bother about inequality constraints.

Observe that for every x such that $Rx = r$ we have

$$\begin{aligned}
c^T x &= -[P^T \bar{\lambda}_\ell + R^T \bar{\lambda}_e]^T x = -\bar{\lambda}_\ell^T [Px] - \bar{\lambda}_e^T [Rx] \\
&= \bar{\lambda}_\ell^T [p - Px] + \underbrace{[-\bar{\lambda}_\ell^T p - \bar{\lambda}_e^T r]}_{\text{const}_P}
\end{aligned}$$

so that (P) is nothing but the problem

$$\text{Opt}(P) = \max_x \{ \bar{\lambda}_\ell^T [p - Px] + \text{const}_P : p - Px \geq 0, Rx = r \}.$$

Let us pass in this problem from the variable x to the variable

$$\xi = p - Px$$

(“primal slack” — vector of residuals in the primal inequality constraints). Observe that the dimension m of this vector, same as the dimension of λ_ℓ , is equal to the number of inequality constraints in (P) . We have already expressed the primal objective in terms of this new variable, and it remains to understand what are the restrictions on this vector imposed by the constraints of (P) . The inequality constraints in (P) want of ξ to be nonnegative; the equality constraints along with the definition of ξ read equivalently that ξ should belong to the image \mathcal{M}_P of the affine subspace $M_P = \{x : Rx = r\} \subset \mathbf{R}^{\dim x}$ under the affine mapping $x \mapsto p - Px$. Let us compute \mathcal{M}_P . The linear subspace \mathcal{L}_P to which M_P is parallel is the image of the linear subspace $L = \{x : Rx = 0\}$ (this is the subspace M_P is parallel to) under the linear mapping $x \mapsto -Px$, or, which is the same, under the mapping $x \mapsto Px$. As a shift vector for \mathcal{M}_P , we can take the image $p - P\bar{x}$ of the vector $\bar{x} \in M_P$ under the affine mapping which maps M_P onto \mathcal{M}_P . We have arrived at the following intermediate result:

(!) *Problem (P) can be reduced to the problem*

$$\begin{aligned} \text{Opt}(\mathcal{P}) &= \max_{\xi \in \mathbf{R}^m} \{ \bar{\lambda}_\ell^T \xi : \xi \geq 0, \xi \in \mathcal{L}_P + \bar{\xi} \} \\ \mathcal{L}_P &= \{Py : Ry = 0\}, \bar{\xi} = p - P\bar{x} \end{aligned} \quad (\mathcal{P})$$

The optimal values of (P) and (\mathcal{P}) are linked by the relation

$$\text{Opt}(P) = \text{Opt}(\mathcal{P}) + \text{const}_P = \text{Opt}(\mathcal{P}) - \bar{\lambda}_\ell^T p + \bar{\lambda}_e^T r.$$

Now let us look at the dual problem (D) , and, similarly to what we did with (P) , let us represent it solely in terms of the “dual slack” λ_ℓ . To this end, observe that if $\lambda = [\lambda_\ell; \lambda_e]$ satisfies the equality constraints in (D) , then

$$\begin{aligned} p^T \lambda_\ell + r^T \lambda_e &= p^T \lambda_\ell + [R\bar{x}]^T \lambda_e = p^T \lambda_\ell + \bar{x}^T [R^T \lambda_e] \\ &= p^T \lambda_\ell + \bar{x}^T [c - P^T \lambda_\ell] = [p - P\bar{x}]^T \lambda_\ell + \underbrace{\bar{x}^T c}_{\text{const}_D} \\ &= \bar{\xi}^T \lambda_\ell + \text{const}_D; \end{aligned}$$

we managed to express the dual objective on the dual feasible set solely in terms of λ_ℓ . Now, the restrictions imposed by the constraints of (D) on λ_ℓ are the nonnegativity: $\lambda_\ell \geq 0$ and the possibility to be extended, by properly chosen λ_e , to a solution to the system of linear equations $P^T \lambda_\ell + R^T \lambda_e = c$. Geometrically, the latter restriction says that λ_ℓ should belong to the affine subspace \mathcal{M}_D which is the image of the affine subspace $M_D = \{[\lambda_\ell; \lambda_e] : P^T \lambda_\ell + R^T \lambda_e = c\}$ under the projection $[\lambda_\ell; \lambda_e] \mapsto \lambda_\ell$. Let us compute \mathcal{M}_D . The linear subspace \mathcal{L}_D to which \mathcal{M}_D is parallel clearly is given as

$$\mathcal{L}_D = \{\lambda_\ell : \exists \lambda_e : P^T \lambda_\ell + R^T \lambda_e = 0\};$$

as a shift vector for \mathcal{M}_D , we can take an arbitrary point in this affine space, e.g., the point $-\bar{\lambda}_\ell$. We have arrived at the following result:

(!!) Problem (D) can be reduced to the problem

$$\begin{aligned} \text{Opt}(\bar{D}) &= \min_{\lambda_\ell \in \mathbf{R}^m} \{ \bar{\xi}^T \lambda_\ell : \lambda_\ell \geq 0, \lambda_\ell \in \mathcal{L}_D - \bar{\lambda}_\ell \} \\ \mathcal{L}_D &= \{ \lambda_\ell : \exists \lambda_e : P^T \lambda_\ell + Q^T \lambda_e = c \} \end{aligned} \quad (\mathcal{D})$$

The optimal values of (D) and (D) are linked by the relation

$$\text{Opt}(D) = \text{Opt}(\mathcal{D}) + \text{const}_D = \text{Opt}(\mathcal{D}) + \bar{x}^T c.$$

Now note that the linear subspaces $\mathcal{L}_P = \{Py : Ry = 0\}$ and $\mathcal{L}_D = \{\lambda_\ell : \exists \lambda_e : P^T \lambda_\ell + R^T \lambda_e = 0\}$ of \mathbf{R}^n are closely related – they are orthogonal complements of each other. Indeed,

$$(\mathcal{L}_P)^\perp = \{ \lambda_\ell : \lambda_\ell^T P y = 0 \ \forall y : Ry = 0 \},$$

that is, $\lambda_\ell \in \mathcal{L}_P^\perp$ if and only if the homogeneous linear equation $(P^T \lambda_\ell)^T y$ in variable y is a consequence of the system of homogeneous linear equations $Ry = 0$; by Linear Algebra, this is the case iff $P^T \lambda_\ell = R^T \mu$ for certain μ , or, setting $\lambda_e = -\mu$, iff $P^T \lambda_\ell + R^T \lambda_e = 0$ for properly chosen λ_e ; but the latter is nothing but the description of \mathcal{L}_D .

We arrive at a wonderful geometric picture:

Problems (P) and (D) are reducible, respectively, to

$$\text{Opt}(\mathcal{P}) = \max_{\xi \in \mathbf{R}^m} \{ \bar{\lambda}_\ell^T \xi : \xi \geq 0, \xi \in \mathcal{M}_P = \mathcal{L}_P + \bar{\xi} \} \quad (\mathcal{P})$$

and

$$\text{Opt}(\mathcal{D}) = \min_{\lambda_\ell \in \mathbf{R}^m} \{ \bar{\xi}^T \lambda_\ell : \lambda_\ell \geq 0, \lambda_\ell \in \mathcal{M}_D = \mathcal{L}_D^\perp - \bar{\lambda}_\ell \}.$$

Both (P) and (D) are the problems of optimizing a linear objective over the intersection of an affine subspace (called primal, resp., dual feasible plane) in \mathbf{R}^m and the nonnegative orthant \mathbf{R}_+^m , and the “geometric data” (the objective and the affine subspace) of the problems are closely related to each other: they are given by a pair of vectors $\bar{\xi}, \bar{\lambda}_\ell$ in \mathbf{R}^m and a pair of linear subspaces $\mathcal{L}_P, \mathcal{L}_D$ which are orthogonal complements to each other. Specifically,

- the feasible planes of (P) and (D) are shifts of the linear subspaces $\mathcal{L}_P = \mathcal{L}_D^\perp$ and $\mathcal{L}_D = \mathcal{L}_P^\perp$, respectively;
- the objective (to be maximized) in (P) is $\bar{\lambda}_\ell^T \xi$, and minus the vector $\bar{\lambda}_\ell$ is also a shift vector for the dual feasible plane \mathcal{M}_D . Similarly, the objective (to be minimized) in (D) is $\bar{\xi}^T \lambda_\ell$, and the vector $\bar{\xi}$ is also a shift vector for the primal feasible plane \mathcal{M}_P

The picture is quite symmetric: geometrically, the dual problem is of the same structure as the primal one, and we see that the problem dual to dual is the primal. Slight asymmetry (the vector $\bar{\lambda}_\ell$ responsible for the primal objective is *minus* the shift vector for the dual problem, while the vector $\bar{\xi}$ responsible for the dual objective is *the* shift for the primal) matches the fact that the primal problem is a maximization, and the dual problem is a minimization one; if we were writing the primal and the dual problem both as maximization or both as minimization programs, the symmetry would be “ideal.”

Now let us look what are, geometrically, the optimal solutions we are looking for. To this end, let us express the duality gap via our slack variables ξ and λ_ℓ . Given feasible for (P) and (D) values of ξ and λ_ℓ , we can associate with them x and λ_e according to

$$\xi = p - Px, \quad Rx = r, \quad P^T \lambda_\ell + R^T \lambda_e = c;$$

clearly, x will be a feasible solution to (P) , and $\lambda = [\lambda_\ell; \lambda_e]$ will be a feasible solution to (D) . Let us compute the corresponding duality gap:

$$\begin{aligned} \text{DualityGap}(x, \lambda) &= [p^T \lambda_\ell + r^T \lambda_e] - c^T x = p^T \lambda_\ell + r^T \lambda_e - [P^T \lambda_\ell + R^T \lambda_e] x \\ &= (p - Px)^T \lambda_\ell + [r - Rx]^T \lambda_e \\ &= \xi^T \lambda_\ell. \end{aligned}$$

Thus, the duality gap is just the inner product of the primal and the dual slacks. Optimality conditions say that feasible solutions to (P) and (D) are optimal for the respective problems iff the duality gap, as evaluated at these solutions, is zero; in terms of (\mathcal{P}) and (\mathcal{Q}) , this means that *a pair of feasible solutions to (\mathcal{P}) and (\mathcal{D}) is comprised of optimal solutions to the respective problems iff these solutions are orthogonal to each other.* Thus,

To solve (\mathcal{P}) and (\mathcal{D}) means to find a pair of orthogonal to each other and nonnegative vectors with the first member of the pair belonging to the affine subspace \mathcal{M}_P , and the second member belonging to the affine subspace \mathcal{M}_D . Here \mathcal{M}_P and \mathcal{M}_D are given affine subspaces in \mathbf{R}^m parallel to the linear subspaces \mathcal{L}_P , \mathcal{L}_D which are orthogonal complements of each other.

Duality Theorem says that this task is feasible iff both \mathcal{M}_P and \mathcal{M}_D do contain nonnegative vectors.

It is a kind of miracle that the purely geometric problem at which we have arrived, with formulation free of any numbers, problem which, modulo its multi-dimensional nature, looks as an ordinary exercise from a high-school textbook on Geometry, is in the focus of research of at least three generations of first-rate scholars, is the subject of dedicated university courses worldwide and, last but not least, possesses huge spectrum of applications ranging from poultry production to signal processing.

A careful reader at this point should ring an alarm: We indeed have shown that a primal-dual pair of LO programs with m inequality constraints in the primal problem and feasible systems of equality constraints can be reduced to the above geometric problem; but how do we now that every instance of the latter problem can indeed be obtained from a primal-dual pair of LO's of the outlined type? This is a legitimate question, and it is easy to answer it affirmatively. Indeed, assume we are given two affine subspaces \mathcal{M}_P and \mathcal{M}_D in \mathbf{R}^m such that the linear subspaces, \mathcal{L}_P and \mathcal{L}_D , to which \mathcal{M}_P and \mathcal{M}_D are parallel, are orthogonal complements of each other: $\mathcal{L}_D = \mathcal{L}_P^\perp$. Then

$$\mathcal{M}_P = \mathcal{L}_P + \bar{\xi} \ \& \ \mathcal{M}_D = \mathcal{L}_P^\perp - \bar{\lambda}_\ell \quad (*)$$

for properly chosen $\bar{\xi}$ and $\bar{\lambda}_\ell$. We can represent \mathcal{L}_P as the kernel of an appropriately chosen matrix R . Consider the LO in the standard form:

$$\max_{\xi} \{ \bar{\lambda}_\ell^T \xi : -\xi \leq 0, R\xi = R\bar{\xi} \},$$

and let us take it as our primal problem (P) . The dual problem (D) then will be

$$\min_{\lambda=[\lambda_\ell; \lambda_e]} \{ [R\bar{\xi}]^T \lambda_e : -\lambda_\ell + R^T \lambda_e = \bar{\lambda}_\ell \}.$$

Clearly, the systems of linear equality constraints in these problems are solvable, one of solutions to the system of linear constraints in (P) being $\bar{\xi}$ (which allows to take

$\bar{x} = \bar{\xi}$), and one of the solutions to the system of linear constraints in (D) being $[-\bar{\lambda}_\ell; 0; \dots; 0]$. It allows to apply to (P) and (D) our machinery to reduce them to problems (\mathcal{P}) , (\mathcal{D}) , respectively. From observations on what can be chosen as feasible solutions to the systems of equality constraints in (P) and in (D) it is immediate to derive (do it!) that the problem (\mathcal{P}) associated with (P) is nothing but (P) itself, so that the its primal feasible affine plane is $\{\xi : R\xi = R\bar{\xi}\}$, which is nothing but $\mathcal{L}_P + \bar{\xi} = \mathcal{M}_P$. Thus, $(P) \equiv (\mathcal{P})$ is nothing but the problem

$$\max_{\xi} \{\bar{\lambda}_\ell^T \xi : \xi \geq 0, \xi \in \mathcal{M}_P = \mathcal{L}_P + \bar{\xi}\}.$$

According to the links between (\mathcal{P}) and (\mathcal{D}) we have established, (\mathcal{D}) is nothing but the problem

$$\min_{\lambda_\ell} \left\{ \bar{\xi}^T \lambda_\ell : \lambda_\ell \geq 0, \lambda_\ell \in \mathcal{L}_P^\perp - \bar{\lambda}_\ell \right\}.$$

The affine feasible plane in (\mathcal{D}) is therefore \mathcal{M}_D (see $(*)$), and our previous analysis shows that the geometric problem associated with (P) , (D) is exactly the problem “pick in the nonnegative parts of \mathcal{M}_P and \mathcal{M}_D vectors which are orthogonal to each other.”

The last question to be addressed is: the pair of problems (\mathcal{P}) , (\mathcal{D}) is specified by a pair \mathcal{M}_P , \mathcal{M}_D of affine subspaces in \mathbf{R}^m (this pair cannot be arbitrary: the parallel to \mathcal{M}_P , \mathcal{M}_D linear subspaces should be orthogonal complements to each other) and a pair of vectors $\bar{\xi} \in \mathcal{M}_P$ and $\bar{\lambda}_\ell \in [-\mathcal{M}_D]$. What happens when we shift these vectors along the corresponding affine subspaces? The answer is: essentially, nothing happens. When $\bar{\lambda}_\ell$ is shifted along $-\mathcal{M}_D$, that is, is replaced with $\bar{\lambda}_\ell + \Delta$ with $\Delta \in \mathcal{L}_D$, the dual problem (\mathcal{D}) remains intact, and the objective of the primal problem (\mathcal{P}) *restricted on the feasible plane \mathcal{M}_P of this problem* is shifted by a constant depending on Δ (check both these claims!); this affects the optimal value of (\mathcal{P}) , but does not affect the optimal set of (\mathcal{P}) . Similarly, when shifting $\bar{\xi}$ along \mathcal{M}_P , the primal problem (\mathcal{P}) remains intact, and the objective of the dual problem (\mathcal{D}) on the feasible plane of this problem is shifted by a constant depending on the shift in $\bar{\xi}$. We could predict this “irrelevance of particular choices of $\bar{\xi} \in \mathcal{M}_P$ and $\bar{\lambda}_\ell \in -\mathcal{M}_D$ ” in advance, since the geometric form of the primal-dual pair (\mathcal{P}) , (\mathcal{D}) of problems: “find a pair of orthogonal to each other nonnegative vectors, one from \mathcal{M}_P and one from \mathcal{M}_D ” is posed solely in terms of \mathcal{M}_P and \mathcal{M}_D .

Our geometric findings are illustrated on figure 3.1.

3.3.3 Extending Calculus of Polyhedral Representability and Robust LO

Polyhedral representability of the cost function of an LO and the support function of a polyhedral set

Consider a LO program in the form

$$\text{Opt}(c, b) = \max_x \{c^T x : Ax \leq b\} \quad [A : m \times n] \quad (3.3.3)$$

which we will denote also as $(P[c, b])$. There are situations when either b , or c , instead of being fixed components of the data, are themselves decision variables in certain “master program” which involves, as a “variable,” the optimal value $\text{Opt}(c, b)$ of (3.3.3) as well.

Figure 3.1: Geometry of primal-dual pair of LO programs. Blue area: feasible set of (\mathcal{P}) — intersection of the 2D primal feasible plane \mathcal{M}_P with the nonnegative orthant \mathbf{R}_+^3 . Red segment: feasible set of (\mathcal{D}) — intersection of the 1D dual feasible plane \mathcal{M}_D with the nonnegative orthant \mathbf{R}_+^3 . Blue dot: primal optimal solution ξ^* . Red dot: dual optimal solution λ_ℓ^* . Pay attention to orthogonality of the primal solution (which is on the z -axis) and the dual solution (which is in the xy -plane).

To give an example, let (3.3.3) be a production planning problem, where b as a vector of resources “consumed” by a factory, x as a production plan, and $\text{Opt}(c, b)$ is the maximum, given the resources, volume of sales. Now imagine that we can buy the resources at certain prices, perhaps under additional restrictions on what can and what cannot be bought (like upper bound on the total cost of ordering the resources, lower and upper bounds on the amounts of every one of resources we can buy, etc.). In this situation the master problem might be to maximize our net profit (volume of sales minus the cost of resources) by choosing both the resources to be used (b) and how to produce (x).

A highly instructive example of a situation where c is varying will be given later (“Robust Optimization”).

In such a situation, in order to handle the master program, we need a polyhedral representation of $\text{Opt}(c, b)$ as a function of the “varying parameter” (b or c) in question.

Opt(c, b) as a function of b . Let us fix c and write $(P_c[b])$ instead of $(P[c, b])$ and $\text{Opt}_c(b)$ instead of $\text{Opt}(c, b)$ to stress the fact that c is fixed and we treat the optimal value of (3.3.3) as a function of the right hand side vector b . Let us make the following assumption:

(!) For some value \bar{b} of b , program $(P_c[b])$ is feasible and bounded.

Then the problem dual to $(P[b])$, that is,

$$\min_{\lambda} \{b^T \lambda : \lambda \geq 0, A^T \lambda = c\} \quad (D_c[b])$$

is feasible when $b = \bar{b}$. But the feasible set of the latter problem does not depend on b , so that, by Weak Duality, $(P_c[b])$ is bounded for all b , and thus $\text{Opt}_c(b)$ is a function taking real values

and, perhaps, the value $-\infty$ (the latter happens at those b for which $(P_c[b])$ is infeasible). Taking into account that a feasible and bounded LO program is solvable, we have the equivalence

$$\text{Opt}_c(b) \geq t \Leftrightarrow \exists x : Ax \leq b \ \& \ c^T x \geq t \quad (3.3.4)$$

which is a polyhedral representation of the *hypograph* $\{[b; t] : t \leq \text{Opt}_c(b)\}$ of $\text{Opt}_c(\cdot)$. As a byproduct, we see that $\text{Opt}_c(\cdot)$ is a *concave* function.

Now, the domain D of $\text{Opt}_c(\cdot)$ – the set of values of b where $\text{Opt}_c(b)$ is a real – clearly is the set of those b 's for which $(P_c[b])$ is feasible (again: under our assumption that program $(P_c[b])$ is feasible and bounded for some $b = \bar{b}$, it follows that the program is solvable whenever it is feasible). Let $\bar{b} \in D$, and let $\bar{\lambda}$ be the optimal solution to the program $(D_c[\bar{b}])$. Then $\bar{\lambda}$ is dual feasible for every program $(P_c[b])$, whence by Weak duality

$$\text{Opt}_c(b) \leq \bar{\lambda}^T b = \bar{\lambda}^T \bar{b} + \bar{\lambda}^T (b - \bar{b}) = \text{Opt}_c(\bar{b}) + \bar{\lambda}^T (b - \bar{b}).$$

The resulting inequality

$$\forall b : \text{Opt}_c(b) \leq \Phi_{\bar{b}}(b) := \text{Opt}_c(\bar{b}) + \bar{\lambda}^T (b - \bar{b}) \quad (3.3.5)$$

resembles the Gradient inequality $f(y) \leq f(x) + (y - x)^T \nabla f(x)$ for smooth concave functions f ; geometrically, it says that the graph of $\text{Opt}_c(b)$ never goes above the graph of the affine function $\Phi_{\bar{b}}(b)$ and touches the latter graph at the point $[\bar{b}; \text{Opt}_c(\bar{b})]$. Now recall that $\text{Opt}_c(b)$ is polyhedrally representable concave function and thus is the restriction on D of the minimum of finitely many affine functions of b :

$$b \in D \Rightarrow \text{Opt}_c(b) = \min_{1 \leq i \leq I} \phi_i(b), \quad \phi_i(b) = \alpha_i^T b + \beta_i.$$

Assuming w.l.o.g. that all these functions are distinct from each other and taking into account that D clearly is full-dimensional (since whenever $b' \geq b \in D$, we have $b' \in D$ as well), we see that $\text{Opt}_c(b)$ is differentiable almost everywhere on D (specifically, everywhere in $\text{int } D$, except for the union of finitely many hyperplanes given by the solvable equations of the form $\phi_i(b) = \phi_j(b)$ with $i \neq j$). At every point $\bar{b} \in \text{int } D$ where $\text{Opt}_c(b)$ is differentiable, (3.3.5) is possible only when $\bar{\lambda} = \nabla \text{Opt}_c(\bar{b})$, and we arrive at the following conclusion:

Let $(P_c(b))$ be feasible and bounded for some b . Then the set $D = \text{Dom } \text{Opt}_c(\cdot)$ is a polyhedral cone with a nonempty interior, and at every point $\bar{b} \in \text{int } D$ where the function $\text{Opt}_c(\cdot)$ is differentiable (and this is so everywhere on $\text{int } D$ except for the union of finitely many hyperplanes), the problem $(D_c[\bar{b}])$ has a unique optimal solution which is the gradient of $\text{Opt}_c(\cdot)$ at \bar{b} .

Of course, we can immediately recognize where the domain D of $\text{Opt}_c(\cdot)$ and the “pieces” $\phi_i(\cdot)$ come from. By Linear Programming Duality Theorem, we have

$$\text{Opt}_c(b) = \min_{\lambda} \{b^T \lambda : \lambda \geq 0, A^T \lambda = c\}.$$

We are in the situation where the feasible domain Λ of the latter problem is nonempty; besides this, it clearly does not contain lines. By Theorem 2.4.1, this feasible domain is

$$\text{Conv}\{\lambda_1, \dots, \lambda_S\} + \text{Cone}\{\rho_1, \dots, \rho_T\},$$

where λ_i are the vertices of Λ , and ρ_j are the (directions of the) extreme rays of $\text{Rec}(\Lambda)$. We clearly have

$$D = \{b : \rho_j^T b \geq 0, 1 \leq j \leq T\}, b \in D \Rightarrow \text{Opt}_c(b) = \min_{1 \leq i \leq S} \lambda_i^T b,$$

so that D is exactly the cone dual to $\text{Rec}(\Lambda)$, and we can take $I = S$ and $\phi_i(b) = \lambda_i^T b$, $1 \leq i \leq S$. Here again we see how powerful are polyhedral representations of functions as compared to their straightforward representations as maxima of affine pieces: the number S of pieces in $\text{Opt}_C(\cdot)$ and the number of linear inequalities specifying the domain of this function can be — and typically are — astronomical, while the polyhedral representation (3.3.4) of the function is fully tractable.

Law of diminishing marginal returns. The concavity of $\text{Opt}_c(b)$ as a function of b , whatever simple this fact be, has important “real life” consequences. Assume, as in the motivating example above, that b is the vector of resources “consumed” by a production process, and we should buy these resources at a market at certain prices p_i forming price vector p . Interpreting the objective in (3.3.3) as our income (the total dollar value of our sales), and denoting by M our investments in the resources, the problem of optimizing the income becomes the LO program

$$\text{Opt}(M) = \max_{x, b} \{c^T x : Ax \leq b, Qb \leq q, p^T b \leq M\},$$

where $Qb \leq q$ are “side constraints” on b (like nonnegativity, upper bounds on the maximal available amounts of various recourses, etc.) In this problem, the right hand side vector is $[q; M]$; we fix once for ever q and treat M as a varying parameter, as expressed by the notation $\text{Opt}(M)$. Note that the feasible set of the problem extends with M ; thus, assuming that the problem is feasible and bounded for certain $M = M_0$, it remains feasible and bounded for $M \geq M_0$. We conclude that $\text{Opt}(M)$ is a finite, nondecreasing and, as we have shown, *concave* function of $M \geq M_0$. Concavity implies that $\text{Opt}(M + \delta) - \text{Opt}(M)$, where $\delta > 0$ is fixed, decreases (perhaps, nonstrictly) as M grows. In other words, *the reward for an extra \$1 in the investment can only decrease as the investment grows*. In Economics, this is called *the law of diminishing marginal returns*.

$\text{Opt}(c, b)$ as a function of c . Now let us treat b as once for ever fixed, and c — as a varying parameter in (3.3.3), and write $(P^b[c])$ instead of (3.3.3) and $\text{Opt}^b(c)$ instead of $\text{Opt}(c, b)$. Assume that $(P^b[c])$ is feasible (this fact is independent of a particular value of c). Then the relation

$$\text{Opt}^b(c) \leq \tau \tag{*}$$

is equivalent to the fact that the problem $(D_c[b])$ is solvable with optimal value $\leq \tau$. Applying the Linear Programming Duality Theorem, we arrive at the equivalence

$$\text{Opt}^b(c) \leq \tau \Leftrightarrow \exists \lambda : A^T \lambda = c, \lambda \geq 0, b^T \lambda \geq \tau; \tag{3.3.6}$$

this equivalence is a polyhedral representation of $\text{Opt}^b(c)$ as a *convex* function. As a byproduct, we see that $\text{Opt}^b(c)$ is convex. The latter could be easily seen from the very beginning: $\text{Opt}^b(c)$ is the supremum of the family $c^T x$ of linear (and thus convex) functions of c over the set $\{x : Ax \leq b\}$ of values of the “parameter” x and thus is convex (see calculus of convex functions).

The above construction works when (3.3.3) is feasible. When it is not the case, the situation is trivial: $\text{Opt}^b(c)$ is $-\infty$ identically, and we do *not* treat such a function as convex (convex

function must take finite values and the value $+\infty$ only); thus, we cannot say that $\text{Opt}^b(c)$ is a “polyhedrally representable convex function,” in spite of the fact that the set of all pairs (c, τ) satisfying $(*)$ – the entire (c, τ) -space! – clearly is polyhedral.

Now let $\bar{c} \in \text{Dom Opt}^b(\cdot)$. Then the problem $(P^b[\bar{c}])$ is feasible and bounded, and thus is solvable. Denoting by \bar{x} an optimal solution to $(P^b[\bar{c}])$ and observing that \bar{x} is feasible for every program $(P^b[c])$, we have

$$\text{Opt}^b(c) \geq c^T \bar{x} = \bar{c}^T \bar{x} + (c - \bar{c})^T \bar{x} = \text{Opt}^b(\bar{c}) + \bar{x}^T (c - \bar{c}),$$

that is,

$$\forall c : \text{Opt}^b(c) \geq \text{Opt}^b(\bar{c}) + \bar{x}^T (c - \bar{c}), \quad (3.3.7)$$

which looks as the Gradient inequality for a smooth convex function. To simplify our analysis, note that if A has a nontrivial kernel, then $\text{Opt}^b(c)$ clearly is $+\infty$ when c is not orthogonal to $\text{Ker } A$; if c is orthogonal to $\text{Ker } A$, then $\text{Opt}^b(c)$ remains intact when we augment the constraints of $(P^b[c])$ with the linear equality constraints $x \in L = (\text{Ker } A)^\perp$. Replacing, if necessary, \mathbf{R}^n with L , let us assume that $\text{Ker } A = 0$, so that the feasible set Π of $(P^b[\cdot])$ does not contain lines. Since it is nonempty, we have

$$\Pi = \text{Conv}\{x_1, \dots, x_S\} + \text{Cone}\{r_1, \dots, r_T\},$$

where x_i are the vertices of Π , and r_j are the (directions of the) extreme rays of $\text{Rec}(\Pi)$. We now clearly have

$$\text{Dom Opt}^b(\cdot) = -(\text{Rec}(\Pi))^*, \quad c \in \text{Dom Opt}^b(\cdot) \Rightarrow \text{Opt}^b(c) = \max_i x_i^T c.$$

Since the cone $\text{Rec}(\Pi)$ is pointed due to $\text{Ker } A = \{0\}$, the domain of $\text{Opt}^b(\cdot)$ possesses a nonempty interior (see the proof of Proposition 2.3.7), and $\text{Opt}^b(c)$ is differentiable everywhere in this interior except for the union of finitely many hyperplanes. This combines with (3.3.7) to imply the following result, completely symmetric to the one we got for $\text{Opt}_c(\cdot)$:

Let $\text{Ker } A = \{0\}$ and $(P^b[\cdot])$ be feasible. Then $P = \text{Dom Opt}_c(\cdot)$ is a polyhedral cone with a nonempty interior, and at every point $\bar{c} \in \text{int } D$ where the function $\text{Opt}^b(\cdot)$ $\text{Opt}_c(\cdot)$ is differentiable (and this is so everywhere on $\text{int } P$ except for the union of finitely many hyperplanes), the problem $(P^b[\bar{c}])$ has a unique optimal solution which is the gradient of $\text{Opt}^b(\cdot)$ at \bar{c} .

Support function of a polyhedral set. Given a nonempty set $X \subset \mathbf{R}^n$, we always can form the function $\text{Supp}_X(c) = \sup_{x \in X} c^T x : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ called *the support function* of X . E.g.,

the above function $\text{Opt}^b(c)$ is the support function of the polyhedral set $X = \{x : Ax \leq b\}$ (which we assume to be nonempty). The support function always is convex (as the supremum of a family of convex functions $c^T x$ of c taken over $x \in X$). In the polyhedral case, the support function “remembers” the set it comes from due to the formula

$$X = \{x \in \mathbf{R}^n : c^T x \leq \text{Supp}_X(c) \ \forall c\}$$

To see its validity, note that the right hand side set, let us call it X' , clearly contains X (indeed, $\text{Supp}_X(c) = \sup_{x \in X} c^T x$, that is, for every c the linear form $c^T x$ is $\leq \text{Supp}_X(c)$ everywhere on X). To see that the inverse inclusion also is true, we should prove that if $\bar{x} \notin X$, then $\bar{x} \notin X'$

as well, that is, there exists a c such that $c^T \bar{x} > \text{Supp}_X(c)$. But this fact is immediately given by the “separation theorem for polyhedral sets:” representing X as $\{x : a_i^T x \leq b_i, 1 \leq i \leq m\}$, the fact that $\bar{x} \notin X$ means that $a_{i_*}^T \bar{x} > b_{i_*}$ for some i_* . Setting $c = a_{i_*}$, we therefore have $c^T \bar{x} > b_{i_*} \geq \text{Supp}_X(c)$, where \geq is evident.

Similar reasoning, with Separation Theorem for convex sets (Theorem 2.4.3) in the role of the (evident!) separation theorem for polyhedral sets, demonstrates that the support function of a nonempty set X remembers this set, *provided that the set is convex and closed*. We complete this section with the following useful modification of the equivalence (3.3.6) which should be considered as a new rule in the calculus of polyhedral sets and polyhedrally representable functions which we started in section 1.2.3. The numeration of calculus rules below continues the one in section 1.2.3.

F.6. *Taking the support function of a polyhedrally representable set:* a polyhedral representation

$$X = \{x \in \mathbf{R}^n : \exists w : Px + Qw \leq r\}$$

of a *nonempty* polyhedral set can be easily converted to a polyhedral representation of its support function:

$$\left\{ [c; \tau] : \tau \geq \text{Supp}_X(c) := \sup_{x \in X} c^T x \right\} = \left\{ [c; \tau] : \exists \lambda : \lambda \geq 0, P^T \lambda = c, Q^T \lambda = 0, r^T \lambda \leq \tau \right\}.$$

To prove the latter relation, note that from the definition of $\text{Supp}_X(c)$ and from the polyhedral representation of X in question it follows immediately that $\text{Supp}_X(c)$ is the optimal value in the (feasible, since X is nonempty) LO program

$$\max_{[x; w]} \{c^T x : Px + Qw \leq r\},$$

and it remains to apply (3.3.6). Note that progress as compared with (3.3.6) is in possibility to build a p.r. of $\text{Supp}_X(\cdot)$ given a *whatever* p.r. of X , while in (3.3.6) X is given by a straightforward p.r. not involving slack variables.

The following two calculus rules are immediate corollaries of F.6:

S.6. A polyhedral representation

$$X = \{x \in \mathbf{R}^n : \exists w : Px + Qw \leq r\}$$

of a polyhedral set containing the origin can be straightforwardly converted into a p.r. of its polar:

$$\begin{aligned} \text{Polar}(X) &:= \{\xi : \xi^T x \leq 1 \forall x \in X\} \\ &= \{\xi : \text{Supp}_X(\xi) \leq 1\} = \{\xi : \exists \lambda : \lambda \geq 0, P^T \lambda = \xi, Q^T \lambda = 0, r^T \lambda \leq 1\}. \end{aligned}$$

S.7. Let X be a polyhedral cone given by a p.r.

$$X = \{x : \exists w : Px + Qw \leq r\}.$$

Then the cone X_* dual to X admits the p.r.

$$\begin{aligned} X_* &:= \{\xi : \xi^T x \geq 0 \forall x \in X\} = \{\xi : \text{Supp}(-\xi) \leq 0\} \\ &= \{\xi : \exists \lambda : \lambda \geq 0, P^T \lambda + \xi = 0, Q^T \lambda = 0, r^T \lambda \leq 0\}. \end{aligned}$$

Applications in Robust LO

Polyhedral representability of $\text{Opt}^b(c)$ plays crucial role in *Robust Linear Optimization* – a (reasonably novel) methodology for handling LO problems with *uncertain* data. Here is the story.

Data uncertainty in LO: sources. Typically, the data of real world LOs

$$\max_x \{c^T x : Ax \leq b\} \quad [A = [a_{ij}] : m \times n] \quad (\text{LO})$$

is not known exactly when the problem is being solved. The most common reasons for data uncertainty are as follows:

- Some of data entries (future demands, returns, etc.) do not exist when the problem is solved and hence are replaced with their forecasts. These data entries are thus subject to *prediction errors*;
- Some of the data (parameters of technological devices/processes, contents associated with raw materials, etc.) cannot be measured exactly, and their true values drift around the measured “nominal” values; these data are subject to *measurement errors*;
- Some of the decision variables (intensities with which we intend to use various technological processes, parameters of physical devices we are designing, etc.) cannot be implemented exactly as computed. The resulting *implementation errors* are equivalent to appropriate artificial data uncertainties.

Indeed, the contribution of a particular decision variable x_j to the left hand side of constraint i is the product $a_{ij}x_j$. A typical implementation error can be modeled as $x_j \mapsto (1 + \xi_j)x_j + \eta_j$, where ξ_j is the multiplicative, and η_j is the additive component of the error. The effect of this error is *as if* there were no implementation error at all, but the coefficient a_{ij} got the multiplicative perturbation: $a_{ij} \mapsto a_{ij}(1 + \xi_j)$, and the right hand side b_i of the constraint got the additive perturbation $b_i \mapsto b_i - \eta_j a_{ij}$.

Data uncertainty: dangers. In the traditional LO methodology, a small data uncertainty (say, 0.1% or less) is just ignored; the problem is solved as *if* the given (“nominal”) data were exact, and the resulting *nominal* optimal solution is what is recommended for use, in hope that small data uncertainties will not affect significantly the feasibility and optimality properties of this solution, or that small adjustments of the nominal solution will be sufficient to make it feasible. In fact these hopes are not necessarily justified, and sometimes even small data uncertainty deserves significant attention. We are about to present two instructive examples of this type.

Motivating example I: Synthesis of Antenna Arrays. Consider a monochromatic transmitting antenna placed at the origin. Physics says that

1. The directional distribution of energy sent by the antenna can be described in terms of *antenna’s diagram* which is a complex-valued function $D(\delta)$ of a 3D direction δ . The directional distribution of energy sent by the antenna is proportional to $|D(\delta)|^2$.
2. When the antenna is comprised of several antenna elements with diagrams $D_1(\delta), \dots, D_k(\delta)$, the diagram of the antenna is just the sum of the diagrams of the elements.

In a typical Antenna Design problem, we are given several antenna elements with diagrams $D_1(\delta), \dots, D_n(\delta)$ and are allowed to multiply these diagrams by complex *weights* x_i (which in reality corresponds to modifying the output powers and shifting the phases of the elements). As a result, we can obtain, as a diagram of the array, any function of the form

$$D(\delta) = \sum_{j=1}^n x_j D_j(\delta),$$

and our goal is to find the weights x_j which result in a diagram as close as possible, in a prescribed sense, to a given “target diagram” $D_*(\delta)$.

Example: Antenna Design. Consider a planar antenna comprised of a central circle and 9 concentric rings of the same area as the circle (figure 3.2.a) in the XY -plane (“Earth’s surface”). Let the wavelength be $\lambda = 50\text{cm}$, and the outer radius of the outer ring be 1 m (twice the wavelength).

One can easily see that the diagram of a ring $\{a \leq r \leq b\}$ in the plane XY (r is the distance from a point to the origin) as a function of a 3-dimensional direction δ depends on the altitude (the angle θ between the direction and the plane) only. The resulting function of θ turns out to be *real-valued*, and its analytic expression is

$$D_{a,b}(\theta) = \frac{1}{2} \int_a^b \left[\int_0^{2\pi} r \cos(2\pi r \lambda^{-1} \cos(\theta) \cos(\phi)) d\phi \right] dr.$$

Fig. 3.2.b represents the diagrams of our 10 rings for $\lambda = 50\text{cm}$.

Assume that our goal is to design an array with a real-valued diagram which should be axial symmetric with respect to the Z -axis and should be “concentrated” in the cone $\pi/2 \geq \theta \geq \pi/2 - \pi/12$. In other words, our target diagram is a real-valued function $D_*(\theta)$ of the altitude θ with $D_*(\theta) = 0$ for $0 \leq \theta \leq \pi/2 - \pi/12$ and $D_*(\theta)$ somehow approaching 1 as θ approaches $\pi/2$. The target diagram $D_*(\theta)$ used in this example is given in figure 3.2.c (blue).

Let us measure the discrepancy between a synthesized diagram and the target one by the Tschebyshev distance, taken along the equidistant 240-point grid of altitudes, i.e., by the quantity

$$\tau = \max_{i=1, \dots, 240} \left| D_*(\theta_i) - \sum_{j=1}^{10} x_j \underbrace{D_{r_{j-1}, r_j}(\theta_i)}_{D_j(\theta_i)} \right|, \quad \theta_i = \frac{i\pi}{480}.$$

Our design problem is simplified considerably by the fact that the diagrams of our “building blocks” and the target diagram are real-valued; thus, we need no complex numbers, and the problem we should finally solve is

$$\min_{\tau \in \mathbf{R}, x \in \mathbf{R}^{10}} \left\{ \tau : -\tau \leq D_*(\theta_i) - \sum_{j=1}^{10} x_j D_j(\theta_i) \leq \tau, i = 1, \dots, 240 \right\}. \quad (3.3.8)$$

This is a simple LP program; its optimal solution x^* results in the diagram depicted at figure 3.2.c (magenta). The uniform distance between the actual and the target diagrams is ≈ 0.0589 (recall that the target diagram varies from 0 to 1).

Now recall that our design variables are characteristics of certain physical devices. In reality, of course, we cannot tune the devices to have precisely the optimal characteristics x_j^* ; the best

Figure 3.2: Synthesis of antennae array.

(a): 10 array elements of equal areas in the XY -plane; the outer radius of the largest ring is 1m, the wavelength is 50cm.

(b): “building blocks” — the diagrams of the rings as functions of the altitude angle θ .

(c): the target diagram (blue) and the synthesized diagram (magenta).

Figure 3.3: “Dream and reality,” nominal optimal design: samples of 100 actual diagrams (red) for different uncertainty levels. Blue: the target diagram

	Dream	Reality								
	$\rho = 0$	$\rho = 0.0001$			$\rho = 0.001$			$\rho = 0.01$		
	value	min	mean	max	min	mean	max	min	mean	max
$\ \cdot\ _\infty$ -distance to target	0.059	1.280	5.671	14.04	11.42	56.84	176.6	39.25	506.5	1484
energy concentration	85.1%	0.5%	16.4%	51.0%	0.1%	16.5%	48.3%	0.5%	14.9%	47.1%

Table 3.1: Quality of nominal antenna design: dream and reality. Data over 100 samples of actuation errors per each uncertainty level ρ .

we may hope for is that the actual characteristics x_j^{fct} will coincide with the desired values x_j^* within a small margin ρ , say, $\rho = 0.1\%$ (this is a fairly high accuracy for a physical device):

$$x_j^{\text{fct}} = (1 + \xi_j)x_j^*, \quad |\xi_j| \leq \rho = 0.001.$$

It is natural to assume that the *actuation errors* ξ_j are random with the mean value equal to 0; it is perhaps not a great sin to assume that these errors are independent of each other. Note that as it was already explained, the consequences of our actuation errors are *as if* there were no actuation errors at all, but the coefficients $D_j(\theta_i)$ of variables x_j in (3.3.8) were subject to perturbations $D_j(\theta_i) \mapsto (1 + \xi_j)D_j(\theta_i)$.

Since the actual weights differ from their desired values x_j^* , the actual (random) diagram of our array of antennae will differ from the “nominal” one we see on figure 3.2.c. How large could be the difference? Looking at figure 3.3, we see that the difference can be dramatic. The diagrams corresponding to $\rho > 0$ are not even the worst case: given ρ , we just have taken as $\{\xi_j\}_{j=1}^{10}$ 100 samples of 10 independent numbers distributed uniformly in $[-\rho, \rho]$ and have plotted the diagrams corresponding to $x_j = (1 + \xi_j)x_j^*$. Pay attention not only to the shape, but also to the scale (table 3.1): the target diagram varies from 0 to 1, and the nominal diagram (the one corresponding to the exact optimal x_j) differs from the target by no more than by 0.0589 (this is the optimal value in the “nominal” problem (3.3.8)). The data in table 3.1 show that when $\rho = 0.001$, the typical $\|\cdot\|_\infty$ distance between the actual diagram and the target one is by 3 (!) orders of magnitude larger. Another meaningful way, also presented in table 3.1, to understand what is the quality of our design is via *energy concentration* – the fraction of the total emitted energy which “goes up,” that is, is emitted along the spatial angle of directions forming angle at most $\pi/12$ with the Z -axis. For the nominal design, *the dream* (i.e., with no actuation errors) energy concentration is as high as 85% – quite respectable, given that the spatial angle in question forms just 3.41% of the entire hemisphere. This high concentration, however, exists only in our imagination, since actuation errors of magnitude ρ as low as 0.01% reduce the average energy concentration (which, same as the diagram itself, now becomes random) to just 16%; the lower 10% quantile of this random quantity is as small as 2.2% – 1.5 times less than the fraction (3.4%) which the “going up” directions form among all directions. The bottom line is that “in reality” our nominal optimal design is completely meaningless.

Motivating example II: NETLIB Case Study NETLIB includes about 100 not very large LOs, mostly of real-world origin, used as the standard benchmark for LO solvers. In the study to be described, we used this collection in order to understand how “stable” are the feasibility properties of the standard – “nominal” – optimal solutions with respect to small uncertainty in the data. To motivate the methodology of this “case study”, here is the constraint # 372 of the

problem PILOT4 from NETLIB:

$$\begin{aligned}
 a^T x &\equiv -15.79081x_{826} - 8.598819x_{827} - 1.88789x_{828} - 1.362417x_{829} - 1.526049x_{830} \\
 &\quad - 0.031883x_{849} - 28.725555x_{850} - 10.792065x_{851} - 0.19004x_{852} - 2.757176x_{853} \\
 &\quad - 12.290832x_{854} + 717.562256x_{855} - 0.057865x_{856} - 3.785417x_{857} - 78.30661x_{858} \\
 &\quad - 122.163055x_{859} - 6.46609x_{860} - 0.48371x_{861} - 0.615264x_{862} - 1.353783x_{863} \\
 &\quad - 84.644257x_{864} - 122.459045x_{865} - 43.15593x_{866} - 1.712592x_{870} - 0.401597x_{871} \\
 &\quad + x_{880} - 0.946049x_{898} - 0.946049x_{916} \\
 &\geq b \equiv 23.387405
 \end{aligned} \tag{C}$$

The related *nonzero* coordinates in the optimal solution x^* of the problem, as reported by CPLEX (one of the best commercial LP solvers), are as follows:

$$\begin{aligned}
 x_{826}^* &= 255.6112787181108 & x_{827}^* &= 6240.488912232100 & x_{828}^* &= 3624.613324098961 \\
 x_{829}^* &= 18.20205065283259 & x_{849}^* &= 174397.0389573037 & x_{870}^* &= 14250.00176680900 \\
 x_{871}^* &= 25910.00731692178 & x_{880}^* &= 104958.3199274139
 \end{aligned}$$

The indicated optimal solution makes (C) an equality within machine precision.

Observe that most of the coefficients in (C) are “ugly reals” like -15.79081 or -84.644257. We have all reasons to believe that coefficients of this type characterize certain technological devices/processes, and as such *they could hardly be known to high accuracy*. It is quite natural to assume that the “ugly coefficients” are in fact uncertain – they coincide with the “true” values of the corresponding data within accuracy of 3-4 digits, not more. The only exception is the coefficient 1 of x_{880} – it perhaps reflects the structure of the underlying model and is therefore exact – “certain”.

Assuming that the uncertain entries of a are, say, 0.1%-accurate approximations of unknown entries of the “true” vector of coefficients \tilde{a} , we looked what would be the effect of this uncertainty on the validity of the “true” constraint $\tilde{a}^T x \geq b$ at x^* . Here is what we have found:

- The minimum (over all vectors of coefficients \tilde{a} compatible with our “0.1%-uncertainty hypothesis”) value of $\tilde{a}^T x^* - b$, is < -104.9 ; in other words, the violation of the constraint can be as large as 450% of the right hand side!

- Treating the above worst-case violation as “too pessimistic” (why should the true values of all uncertain coefficients differ from the values indicated in (C) in the “most dangerous” way?), consider a more realistic measure of violation. Specifically, assume that the true values of the uncertain coefficients in (C) are obtained from the “nominal values” (those shown in (C)) by random perturbations $a_j \mapsto \tilde{a}_j = (1 + \xi_j)a_j$ with independent and, say, uniformly distributed on $[-0.001, 0.001]$ “relative perturbations” ξ_j . What will be a “typical” relative violation

$$V = \frac{\max[b - \tilde{a}^T x^*, 0]}{b} \times 100\%$$

of the “true” (now random) constraint $\tilde{a}^T x \geq b$ at x^* ? The answer is nearly as bad as for the worst scenario:

Prob{ $V > 0$ }	Prob{ $V > 150\%$ }	Mean(V)
0.50	0.18	125%

Relative violation of constraint # 372 in PILOT4

(1,000-element sample of 0.1% perturbations of the uncertain data)

We see that *quite small (just 0.1%) perturbations of “clearly uncertain” data coefficients can make the “nominal” optimal solution x^* heavily infeasible and thus – practically meaningless.*

A “case study” reported in [2] shows that the phenomenon we have just described is not an exception – in 13 of 90 *NETLIB* Linear Programming problems considered in this study, already 0.01%-perturbations of “ugly” coefficients result in violations of some constraints as evaluated at the nominal optimal solutions by more than 50%. In 6 of these 13 problems the magnitude of constraint violations was over 100%, and in *PILOT4* — “the champion” — it was as large as 210,000%, that is, 7 orders of magnitude larger than the relative perturbations in the data.

The conclusion is as follows:

In applications of LO, there exists a real need of a technique capable of detecting cases when data uncertainty can heavily affect the quality of the nominal solution, and in these cases to generate a “reliable” solution, one that is immunized against uncertainty.

Uncertain Linear Problems and their Robust Counterparts. We are about to introduce the *Robust Counterpart* approach to uncertain LO problems aimed at coping with data uncertainty.

Uncertain LO problem. We start with

Definition 3.3.1 *An uncertain Linear Optimization problem is a collection*

$$\left\{ \max_x \{c^T x + d : Ax \leq b\} \right\}_{(c,d,A,b) \in \mathcal{U}} \quad (LO_{\mathcal{U}})$$

of LO problems (instances) $\min_x \{c^T x + d : Ax \leq b\}$ of common structure (i.e., with common numbers m of constraints and n of variables) with the data varying in a given uncertainty set $\mathcal{U} \subset \mathbf{R}^{(m+1) \times (n+1)}$.

We always assume that the uncertainty set is parameterized, in an affine fashion, by *perturbation vector* ζ varying in a given *perturbation set* \mathcal{Z} :

$$\mathcal{U} = \left\{ \left[\begin{array}{c|c} c^T & d \\ \hline A & b \end{array} \right] = \underbrace{\left[\begin{array}{c|c} c_0^T & d_0 \\ \hline A_0 & b_0 \end{array} \right]}_{\substack{\text{nominal} \\ \text{data } D_0}} + \sum_{\ell=1}^L \zeta_{\ell} \underbrace{\left[\begin{array}{c|c} c_{\ell}^T & d_{\ell} \\ \hline A_{\ell} & b_{\ell} \end{array} \right]}_{\substack{\text{basic} \\ \text{shifts } D_{\ell}}} : \zeta \in \mathcal{Z} \subset \mathbf{R}^L \right\}. \quad (3.3.9)$$

For example, when speaking about *PILOT4*, we, for the sake of simplicity, tacitly assumed uncertainty only in the constraint matrix, specifically, as follows: every coefficient a_{ij} is allowed to vary, independently of all other coefficients, in the interval $[a_{ij}^n - \rho_{ij}|a_{ij}^n|, a_{ij}^n + \rho_{ij}|a_{ij}^n|]$, where a_{ij}^n is the nominal value of the coefficient — the one in the data file of the problem as presented in *NETLIB*, and ρ_{ij} is the perturbation level, which in our experiment was set to 0.001 for all “ugly” coefficients a_{ij}^n and was set to 0 for “nice” coefficients, like the coefficient 1 at x_{880} . Geometrically, the corresponding perturbation set is just a box

$$\zeta \in \mathcal{Z} = \{\zeta = \{\zeta_{ij} \in [-1, 1]\}_{i,j: a_{ij}^n \text{ is ugly}}\},$$

and the parameterization of the a_{ij} -data by the perturbation vector is

$$a_{ij} = \begin{cases} a_{ij}^n(1 + \zeta_{ij}), & a_{ij}^n \text{ is ugly} \\ a_{ij}^n, & \text{otherwise} \end{cases}$$

Robust Counterpart of Uncertain LO. Note that a *family* of optimization problems like $(LO_{\mathcal{U}})$, in contrast to a single optimization problem, is not associated by itself with the concepts of feasible/optimal solution and optimal value. How to define these concepts depends on the underlying “decision environment.” Here we focus on an environment with the following characteristics:

- A.1. All decision variables in $(LO_{\mathcal{U}})$ represent “here and now” decisions; they should be assigned specific numerical values as a result of solving the problem *before* the actual data “reveals itself.”
- A.2. The decision maker is fully responsible for consequences of the decisions to be made when, and only when, the actual data is within the prespecified uncertainty set \mathcal{U} given by (3.3.9).
- A.3. The constraints in $(LO_{\mathcal{U}})$ are “hard” — we cannot tolerate violations of constraints, even small ones, when the data is in \mathcal{U} .

Note that A.1 – A.3 are *assumptions* on our decision environment (in fact, the strongest ones within the methodology we are presenting); while being meaningful, these assumptions in no sense are automatically valid; In the mean time, we shall consider relaxed versions of these assumptions and consequences of these relaxations.

Assumptions A.1 — A.3 determine, essentially in a unique fashion, what are the meaningful, “immunized against uncertainty,” feasible solutions to the uncertain problem $(LO_{\mathcal{U}})$. By A.1, these should be fixed vectors; by A.2 and A.3, they should be *robust feasible*, that is, they should satisfy all the constraints, whatever the realization of the data from the uncertainty set. We have arrived at the following definition.

Definition 3.3.2 A vector $x \in \mathbf{R}^n$ is a *robust feasible solution* to $(LO_{\mathcal{U}})$, if it satisfies all realizations of the constraints from the uncertainty set, that is,

$$Ax \leq b \quad \forall (c, d, A, b) \in \mathcal{U}. \quad (3.3.10)$$

As for the objective value to be associated with a robust feasible) solution, assumptions A.1 — A.3 do not prescribe it in a unique fashion. However, “the spirit” of these worst-case-oriented assumptions leads naturally to the following definition:

Definition 3.3.3 Given a candidate solution x , the *robust value* $\widehat{c}(x)$ of the objective in $(LO_{\mathcal{U}})$ at x is the smallest value of the “true” objective $c^T x + d$ over all realizations of the data from the uncertainty set:

$$\widehat{c}(x) = \inf_{(c, d, A, b) \in \mathcal{U}} [c^T x + d]. \quad (3.3.11)$$

After we agree what are meaningful candidate solutions to the uncertain problem $(LO_{\mathcal{U}})$ and how to quantify their quality, we can seek the best robust value of the objective among all robust feasible solutions to the problem. This brings us to the central concept of the RO methodology, *Robust Counterpart* of an uncertain optimization problem, which is defined as follows:

Definition 3.3.4 The *Robust Counterpart of the uncertain LO problem* $(LO_{\mathcal{U}})$ is the optimization problem

$$\max_x \left\{ \widehat{c}(x) = \inf_{(c, d, A, b) \in \mathcal{U}} [c^T x + d] : Ax \leq b \quad \forall (c, d, A, b) \in \mathcal{U} \right\} \quad (3.3.12)$$

of maximizing the robust value of the objective over all robust feasible solutions to the uncertain problem.

An optimal solution to the Robust Counterpart is called a robust optimal solution to (LO_U) , and the optimal value of the Robust Counterpart is called the robust optimal value of (LO_U) .

In a nutshell, the robust optimal solution is simply “the best uncertainty-immunized” solution we can associate with our uncertain problem.

Tractability of the RC. In order for the outlined methodology to be a practical tool rather than a wishful thinking, the RO of an uncertain LO problem should be efficiently solvable. We believe (and this belief will be justified in the “algorithmic” part of our course) that LO programs are efficiently solvable; but the RO of uncertain LO problem, as it appears in (3.3.12), is *not* an LO program — when the uncertainty set \mathcal{U} is infinite (which typically is the case), (3.3.12) is an optimization program with *infinitely many* linear inequality constraints, parameterized by the uncertain data! And programs of this type (the so called *semi-infinite* LO’s – not necessarily are tractable...

The situation, however, is not that bad. We are about to demonstrate — and this is where the equivalence (3.3.6) is instrumental — that *the Robust Counterpart of an uncertain LO problem with a nonempty polyhedral uncertainty set \mathcal{U}* (given by its polyhedral representation) is *equivalent to an explicit LO program* (and thus is computationally tractable).

The reasoning goes as follows. Introducing slack variable t , we can rewrite (3.3.12) as the problem with “certain” linear objective and semi-infinite constraints:

$$\max_{y=[x;t]} \left\{ t : \begin{array}{l} t - c^T x - d \leq 0 \\ \sum_j a_{ij} x_j - b_j \leq 0, 1 \leq j \leq m \end{array} \right\} \forall (c, d, A, b) \in \mathcal{U}. \quad (!)$$

To save notation, let η stand for the data (c, d, A, b) which we can treat as a vector of certain dimension N (in this vector, the first n entries are those of c , the next entry is d , the next mn entries are the coefficients of the constraint matrix, written, say, column by column, and the last m entries are those of b). Note that (!) is of the generic form

$$\max_y \{ h^T y : \forall \eta \in \mathcal{U} : p_\ell^T[y] \eta \leq q_\ell[y], 1 \leq \ell \leq L \} \quad (!!)$$

where $L = m + 1$, and $p_\ell[y]$, $q_\ell[y]$ are known *affine* vector- and real-valued functions of y . All we need in order to convert (!!) into an ordinary LO, is to represent every one of the semi-infinite constraints

$$p_\ell^T[y] \eta \leq q_\ell[y] \quad \forall \eta \in \mathcal{U} \quad (*_\ell)$$

with a finite system of linear inequalities on y and on appropriate slack variables. Now, for every ℓ and y fixed, $(*_\ell)$ says that

$$\sup_{\eta \in \mathcal{U}} p_\ell^T[y] \eta \leq q_\ell[y]; \quad (**)$$

Recalling that \mathcal{U} is polyhedral and we are given a polyhedral representation of this set, let it be

$$\mathcal{U} = \{ \eta : \exists u : P\eta + Qu + r \leq 0 \},$$

the supremum in η in the left hand side of (**) can be represented as the optimal value in an LO program in variables η, u , specifically, the program

$$\text{Opt}(y) = \max_{\eta, u} \{ p_\ell^T[y] \eta : P\eta + Qu \leq r \}.$$

This program is feasible (since \mathcal{U} is nonempty), and we can invoke the equivalence (3.3.6) to conclude that

$$\text{Opt}(y) \leq q_\ell(y) \Leftrightarrow \exists w : w \geq 0, [P; Q]^T w = [p_\ell[y]; \underbrace{0; \dots; 0}_{\dim u}], r^T w \leq q_\ell[y].$$

The bottom line is that y satisfies $(*_\ell)$ if and only if it can be extended, by a properly chosen $w = w^\ell$, to a feasible solution to the system of linear inequalities

$$w^\ell \geq 0, P^T w^\ell = p_\ell[y], Q^T w^\ell = 0, r^T w^\ell \leq q_\ell[y] \quad (S_\ell)$$

in variables y, w^ℓ (to see that the inequalities indeed are linear, note that $p_\ell[y]$ and $q_\ell[y]$ are affine in y).

We are done: replacing every one of the L semi-infinite constraints in (II) with the corresponding systems (S_ℓ) , $\ell = 1, \dots, L$, we end up with an equivalent reformulation of (II) as an LO program in variables y, w^1, \dots, w^L . Note that given a polyhedral representation of \mathcal{U} , building the resulting LO is a purely algorithmic and efficient process, and that the sizes of this LO are polynomial in the sizes of the instances of the original uncertain LO problem and the sizes of the polyhedral description of the uncertainty set.

How it works: Robust Antenna Design. In the situation of the Antenna Design problem (3.3.8), the “physical” uncertainty comes from the actuation errors $x_j \mapsto (1 + \xi_j)x_j$; as we have already explained, these errors can be modeled equivalently by the perturbations $D_j(\theta_i) \mapsto D_{ij} = (1 + \xi_j)D_j(\theta_i)$ in the coefficients of x_j . Assuming that the errors ξ_j are bounded by a given *uncertainty level* ρ , and that this is the only a priori information on the actuation errors, we end up with the uncertain LO problem

$$\left\{ \min_{x, \tau} \left\{ \tau : -\tau \leq \sum_{j=1}^{J=10} D_{ij} x_j - D_*(\theta_i) \leq \tau, 1 \leq i \leq I = 240 \right\} : |D_{ij} - D_j(\theta_i)| \leq \rho |D_j(\theta_i)| \right\}.$$

The Robust Counterpart of the problem is the semi-infinite LO program

$$\min_{x, \tau} \left\{ \tau : -\tau \leq \sum_j D_{ij} x_j \leq \tau, 1 \leq i \leq I \forall D_{ij} \in [\underline{G}_{ij}, \overline{G}_{ij}] \right\} \quad (3.3.13)$$

with $\underline{G}_{ij} = G_j(\theta_i) - \rho |G_j(\theta_i)|$, $\overline{G}_{ij} = G_j(\theta_i) + \rho |G_j(\theta_i)|$. The generic form of this semi-infinite LO is

$$\min_y \{ c^T y : Ay \leq b \forall [A, b] : [\underline{A}, \underline{b}] \leq [A, b] \leq [\overline{A}, \overline{b}] \} \quad (3.3.14)$$

where \leq for matrices is understood entrywise and $[\underline{A}, \underline{b}] \leq [\overline{A}, \overline{b}]$ are two given matrices. This is a very special case of a polyhedral uncertainty set, so that our theory says that the RC is equivalent to an explicit LO program. In fact we can point out (one of) LO reformulation of the Robust Counterpart without reference to any theory: it is easy to see (check it!) that (3.3.14) is equivalent to the LO program

$$\min_{y, z} \{ c^T y : \underline{A}z + \overline{A}(y + z) \leq \underline{b}, z \geq 0, y + z \geq 0 \}. \quad (3.3.15)$$

Figure 3.4: “Dream and reality,” robust optimal design: samples of 100 actual diagrams (red) for different uncertainty levels. Blue: the target diagram.

	Reality								
	$\rho = 0.01$			$\rho = 0.05$			$\rho = 0.1$		
	min	mean	max	min	mean	max	min	mean	max
$\ \cdot\ _\infty$ -distance to target	0.075	0.078	0.081	0.077	0.088	0.114	0.082	0.113	0.216
energy concentration	70.3%	72.3%	73.8%	63.6%	71.6%	79.3%	52.2%	70.8%	87.5%

Table 3.2: Quality of robust antenna design. Data over 100 samples of actuation errors per each uncertainty level ρ .

For comparison: for nominal design, with the uncertainty level as small as $\rho = 0.001$, the average $\|\cdot\|_\infty$ -distance of the actual diagram to target is as large as 56.8, and the expected energy concentration is as low as 16.5%.

Solving (3.3.13) for the uncertainty level $\rho = 0.01$, we end up with the robust optimal value 0.0815, which, while being by 39% worse than the nominal optimal value 0.0589 (the latter, as we have seen, exists only in our imagination and says nothing about the actual performance of the nominal optimal design), still is reasonably small. Note that the robust optimal value, in sharp contrast with the nominally optimal one, does say something meaningful about the actual performance of the underlying *robust* design. In our experiments, we have tested the robust optimal design associated with the uncertainty level $\rho = 0.01$ versus actuation errors of this and larger magnitudes. The results are presented on figure 3.4 and in table 3.2. Comparing these figure and table with their “nominal design” counterparts, we see that the robust design is incomparably better than the nominal one.

NETLIB Case Study The corresponding uncertainty model (“ugly coefficients a_{ij} in the constraint matrix independently of each other run through the segments $[a_{ij}^n - \rho|a_{ij}^n|, a_{ij}^n + \rho|a_{ij}^n|]$, $\rho > 0$ being the uncertainty level) clearly yields the RCs of the generic form (3.3.14). As explained above, these RCs can be straightforwardly converted to explicit LO programs which are of nearly the same sizes and sparsity as the instances of the uncertain LOs in question. It

turns out that at the uncertainty level 0.1% ($\rho = 0.001$), all these RCs are feasible, that is, we can immunize the solutions against this uncertainty. Surprisingly, this immunization is “nearly costless” – the robust optimal values of all 90 NETLIB LOs considered in [2] remain within 1% margin of the nominal optimal values. For further details, including what happens at larger uncertainty levels, see [2].

3.3.4 Extending Calculus of Polyhedral Representability: Majorization

Preliminaries

We start with introducing two useful functions on \mathbf{R}^n . Given an integer k , $1 \leq k \leq n$, let us set

$$s_k(x) = \text{sum of the } k \text{ largest entries in } x$$

and

$$\|x\|_{k,1} = \text{sum of the } k \text{ largest magnitudes of entries in } x$$

(we already met with the latter function, see p. 19). For example,

$$s_2([3; 1; 2]) = 3 + 2 = 5, \quad s_2([3, 3, 1]) = 3 + 3 = 6, \quad \|[5, -1, -7]\|_{2,1} = 7 + 5 = 12.$$

We intend to demonstrate that these functions are polyhedrally representable, and to build their p.r.’s.

Function $s_k(\cdot)$. Let S_k be the set of all Boolean vectors (i.e., those with coordinates 0 and 1) in \mathbf{R}^n which have exactly k coordinates equal to 1. We clearly have

$$s_k(x) = \max_{y \in S_k} y^T x. \quad (*)$$

Now, by the result stated in Exercise 2.5, S_k is exactly the set of vertices of the polyhedral set

$$Y = \{y \in \mathbf{R}^n : 0 \leq y_i \leq 1, 1 \leq i \leq n, \sum_i y_i = k\};$$

since X is bounded and thus is the convex hull of its vertices, $(*)$ says that $s_k(x)$ is the support function of Y :

$$s_k(x) = \max_y \left\{ x^T y : 0 \leq y_i \leq 1, 1 \leq i \leq n, \sum_i y_i = k \right\},$$

so that a polyhedral representation of $s_k(\cdot)$ is readily given by the results of section 3.3.3. Applying (3.3.6) and denoting $\lambda^-, \lambda^+, \mu$ the (vectors of) Lagrange multipliers associated with the constraints $y \geq 0$, $y \leq [1; \dots; 1]$ and $\sum_i y_i = k$, respectively, we get

$$\{[x; \tau] : \tau \geq s_k(x)\} = \{[x; \tau] : \exists(\lambda^- \leq 0, \lambda^+ \geq 0, \mu) : \lambda^- + \lambda^+ + \mu[1; \dots; 1] = x, \sum_i \lambda_i^+ + k\mu \leq \tau\},$$

which clearly simplifies to

$$\{[x; \tau] : \tau \geq s_k(x)\} = \{[x; \tau] : \exists \lambda, \mu : x_i \leq \lambda_i + \mu, 1 \leq i \leq n, \tau \geq \sum_{i=1}^n \lambda_i + k\mu, \lambda_i \geq 0 \forall i\}. \quad (3.3.16)$$

We have built a p.r. for $s_k(\cdot)$.

Remark: since the functions $s_k(x)$ are p.r.f., so are the functions $s_{n-k}(x) - \sum_{i=1}^n x_i$, meaning that the sum $\underline{s}_k(x)$ of k smallest entries of $x \in \mathbf{R}^n$ is a concave polyhedrally representable function of x (indeed, $\underline{s}_k(x) = \sum_{i=1}^n x_i - s_{n-k}(x)$). What is important in these convexity/concavity results, is that we speak about sums of k largest/smallest entries in x , not about the k -th largest (or k -th smallest) entry in x . One can demonstrate by examples that the k -th largest entry $x^k(x)$ of a vector $x \in \mathbf{R}^n$ is neither concave, nor convex function of x , unless $k = 1$ ($x^1(x) = s_1(x)$ is convex) or $k = n$ ($x^n(x) = \underline{s}_1(x)$ is concave).

Function $\|x\|_{k,1}$. Denoting $|x| = [|x_1|; \dots; |x_n|]$, we clearly have $\|x\|_{k,1} = s_k(|x|)$, which combines with (3.3.16) to imply that

$$\{[x; \tau] : \tau \geq \|x\|_{k,1}\} = \{[x; \tau] : \exists \lambda, \mu : \pm x_i \leq \lambda_i + \mu, 1 \leq i \leq n, \tau \geq \sum_{i=1}^n \lambda_i + k\mu, \lambda_i \geq 0 \forall i\}. \quad (3.3.17)$$

which is a p.r. for $\|x\|_{k,1}$.

Majorization

Postponing for a moment functions $s_k(\cdot)$, let us look at something seemingly completely different — at the set Π_n of double stochastic $n \times n$ matrices (see p. 78). Recall that this is the polyhedral set in the space $\mathbf{R}^{n \times n} = \mathbf{R}^{n^2}$ of $n \times n$ matrices P given by the constraints

$$\Pi_n = \{P \in \mathbf{R}^{n \times n} : P_{ij} \geq 0 \forall i, j, \sum_i P_{ij} = 1 \forall j, \sum_j P_{ij} = 1 \forall i\}.$$

Birkhoff's Theorem (Theorem 2.3.1) states that the vertices of Π_n are exactly the permutation $n \times n$ matrices. Since Π_n clearly is bounded, it is the convex hull of the set of its vertices, and we arrive at the following useful result:

An $n \times n$ matrix is double stochastic iff it is a convex combination of $n \times n$ permutation matrices.

We now make the following

Observation 3.3.1 *Let f be a convex and symmetric function on \mathbf{R}^n , the symmetry meaning that whenever x' is obtained from x by permuting the entries, one has $f(x') = f(x)$. Then for every x and every double stochastic matrix P one has*

$$f(Px) \leq f(x). \quad (3.3.18)$$

Verification is immediate: if P is double stochastic, then $P = \sum_i \lambda_i P^i$, where P^i are permutation matrices and λ_i are nonnegative weights summing up to 1. It follows that

$$f(Px) = f\left(\sum_i \lambda_i P^i x\right) \underbrace{\leq}_{(a)} \sum_i \lambda_i f(P^i x) \underbrace{=}_{(b)} \sum_i \lambda_i f(x) = f(x),$$

where (a) is given by Jensen's inequality and (b) is due to the symmetry of f . \square

Observation 3.3.1 is the source of numerous useful inequalities. For starters, here is the derivation of the famous inequality between the arithmetic and the geometric means:

For nonnegative reals x_1, \dots, x_n it always holds

$$\frac{x_1 + \dots + x_n}{n} \geq (x_1 x_2 \dots x_n)^{1/n}.$$

Indeed, it is not difficult to prove that the function $g(x) = (x_1 \dots x_n)^{1/n}$ is concave in the nonnegative orthant, and of course it is symmetric. Given an $x \geq 0$, specifying P as the $n \times n$ matrix with all entries equal to $1/n$ (this clearly is a double stochastic matrix) and applying (3.3.18) to x , P and the convex symmetric function $f = -g$, we get

$$g(Px) \geq g(x);$$

but $g(Px)$ clearly is the arithmetic mean of x_1, \dots, x_n , and we are done.

We can get in the same fashion the inequality between the arithmetic and the harmonic means:

For positive reals x_1, \dots, x_n it always holds

$$\frac{n}{\frac{1}{x_1} + \frac{1}{x_2} + \dots + \frac{1}{x_n}} \leq \frac{x_1 + \dots + x_n}{n}$$

Indeed, it is easy to see that the function $f(x) = \frac{1}{x_1} + \dots + \frac{1}{x_n}$, regarded as a function of a positive vector x (i.e., extended by the value $+\infty$ outside the set of positive vectors), is convex (and of course symmetric). Given $x > 0$ and using the same P as above, we get from (3.3.18) as applied to x, P, f that

$$\frac{n^2}{x_1 + \dots + x_n} \leq \frac{1}{x_1} + \dots + \frac{1}{x_n},$$

which is nothing but (*).

In fact both these inequalities can be easily obtained directly from the Jensen inequality and do not need “a cannon” like Birkhoff’s Theorem⁵ This is not so in our next example:

(!) Let \mathbf{S}^n be the space of symmetric $n \times n$ matrices; for a matrix $X \in \mathbf{S}^n$, let $\lambda(X) \in \mathbf{R}^n$ be the vector of eigenvalues $\lambda_i(X)$ of X (taken with their multiplicities in the non-ascending order). For every convex and symmetric function f on \mathbf{R}^n , the function $F(X) = f(\lambda(X))$ on \mathbf{S}^n is convex.

To justify this claim it suffices to verify the following, important by its own right, relation:

$$F(X) = \sup_{U \in \mathcal{O}_n} f(\text{diag}(UXU^T)), \quad (!!)$$

where \mathcal{O}_n is the set of all orthogonal $n \times n$ matrices, and $\text{diag}(Y)$ is the vector comprised of the diagonal entries of a matrix Y . Indeed, taking (!!) for granted, we observe that $f(\text{diag}(UXU^T))$ is convex along with f (calculus of convex functions, rule on affine substitution of argument). It remains to recall that the supremum of a whatever family of convex functions is convex as well.

To prove (!), note that by the eigenvalue decomposition, a symmetric matrix X can be represented as $X = V\Lambda V^T$, where V is orthogonal and Λ is the diagonal matrix with the eigenvalues of X on the diagonal. Denoting temporarily the right hand side in (!!) by $G(X)$,

⁵Indeed, when proving the arithmetic-geometric means inequality, we lose nothing by assuming that $x > 0$ and $\sum_i x_i = n$. Applying Jensen’s inequality to the (clearly convex) function $-\ln(s)$ on the positive ray, we get $0 = -\ln(\frac{x_1 + \dots + x_n}{n}) \leq \frac{1}{n}[-\ln(x_1) - \dots - \ln(x_n)] = -\ln([x_1 \dots x_n]^{1/n})$, which is the same as the inequality we need.

we clearly have $G(X) \geq F(X) \equiv f(\lambda(X))$ (take $U = V^T$). To prove the opposite inequality, note that when U is orthogonal, we have $UXU^T = U(V\Lambda V^T)U^T = W\Lambda W^T$, where $W = UV$ is orthogonal along with U, V . It follows that

$$(UXU^T)_{ii} = \sum_{j,\ell} W_{ij}\Lambda_{j\ell}[W^T]_{\ell i} = \sum_{j=1}^n W_{ij}^2 \lambda_j(X).$$

Since W is orthogonal, the matrix $P = [W_{ij}^2]_{1 \leq i,j \leq n}$ is double stochastic. We see that the diagonal of UXU^T is the product of a double stochastic matrix and the vector of eigenvalues of X , whence, by (3.3.18), $f(\text{diag}(UXU^T)) \leq f(\lambda(X))$ (recall that f is symmetric and convex). The latter inequality holds true for every orthogonal U , whence $G(X) = \sup_{U \in \mathcal{O}_n} f(\text{diag}(UXU^T)) \leq f(\lambda(X)) = F(X)$. \square

The results above imply numerous useful and by far non-evident at the first glance facts, like

- The sum of $k \leq n$ largest eigenvalues of a symmetric $n \times n$ matrix X is a convex function of X , and its value at X is \geq the sum of the k largest diagonal entries in X (use (!) – (!!)) with $f = s_k$). Similar result holds for the sums of k largest magnitudes of eigenvalues and k largest magnitudes of the diagonal entries of X ;
- The functions $\text{Det}^{1/n}(X)$ and $\ln(\text{Det}(X))$, regarded as functions of positive semidefinite (all eigenvalues are nonnegative, or, equivalently, $\xi^T X \xi \geq 0$ for all ξ) symmetric $n \times n$ matrix X are concave, and $\text{Det}(X)$ is \leq the product of the diagonal entries of X (use (!) – (!!)) with the functions $f(s) = (s_1 \dots s_n)^{1/n}$ and $f(s) = \sum_i \ln s_i$, $s \geq 0$);
- The function $\text{Det}^{-1}(X)$, regarded as a function of positive definite (all eigenvalues positive) symmetric matrix X is convex,

to name just a few.

Majorization Principle

Observation 3.3.1 attracts our attention to the following question:

Given $x, y \in \mathbf{R}^n$, when y can be represented as Px with a double stochastic matrix P ?

The answer is given by

Theorem 3.3.1 [Majorization Principle] *A vector $y \in \mathbf{R}^n$ is the image of a vector $x \in \mathbf{R}^n$ under multiplication by a double stochastic matrix iff*

$$s_k(y) \leq s_k(x), 1 \leq k < n \text{ \& } s_n(y) = s_n(x). \quad (3.3.19)$$

Proof. *Necessity:* let $y = Px$ for a double stochastic P . Then $s_k(y) \leq s_k(x)$, $1 \leq k \leq n$, by Observation 3.3.1, since $s_k(\cdot)$ is convex (we have seen it) and clearly is symmetric. And of course multiplication by a double stochastic matrix preserves the sum of entries in a vector:

$$\sum_i (Px)_i = [1; \dots; 1]^T Px = (P^T [1; \dots; 1])^T x = [1; \dots; 1]^T x; \quad 6$$

⁶to understand the equalities, note that if P is double stochastic, then so is P^T , and the product of a double stochastic matrix by the all-1 vector is this very vector.

so that $s_n(Px) = s_n(x)$.

Sufficiency: Assume that (3.3.19) holds true, and let us prove that $y = Px$ for some double stochastic matrix P . Both the existence of the representation in question and the validity of (3.3.19) are preserved when we permute entries in x and permute, perhaps differently, entries in y . Thus, in addition to (3.3.19), we can assume w.l.o.g. that

$$x_1 \geq x_2 \geq \dots \geq x_n, y_1 \geq y_2 \geq \dots \geq y_n.$$

Now suppose that the representation we are looking for does not exist: $y \notin X = \{Px : P \in \Pi_n\}$, and let us lead this assumption to a contradiction. Since Π_n is polyhedral, so is X (as the image of Π_n under the linear mapping $P \mapsto Px$). Since $y \notin X$ and X is polyhedral, there exists a nonstrict linear inequality which is valid on X and is violated at y , or, equivalently, there exists $\xi \in \mathbf{R}^n$ such that

$$\xi^T y > \max_{x' \in X} \xi^T x'. \quad (!)$$

Now, if $\xi_i < \xi_j$ for i, j such that $i < j$, then, permuting i -th and j -th entry in ξ , the right hand side in (!) remains intact (since X clearly is closed w.r.t. permutations of entries in a vector), and the left hand side does not decrease (check it, keeping in mind that $\xi_i < \xi_j$ and $y_i \geq y_j$ due to $i < j$). It follows that arranging the entries in ξ in the non-ascending order, we keep intact the right hand side in (!) and can only increase the left hand side, that is, (!) remains valid. The bottom line is that we can assume that $\xi_1 \geq \xi_2 \geq \dots \geq \xi_n$. Now comes the punch line: since y_i are in the non-ascending order, we have $s_k(y) = y_1 + \dots + y_k$, whence

$$y_k = s_k(y) - s_{k-1}(y), \quad 2 \leq k \leq n,$$

so that

$$\begin{aligned} \xi^T y &= \xi_1 s_1(y) + \xi_2 [s_2(y) - s_1(y)] + \xi_3 [s_3(y) - s_2(y)] + \dots + \xi_n [s_n(y) - s_{n-1}(y)] \\ &= [\xi_1 - \xi_2] s_1(y) + [\xi_2 - \xi_3] s_2(y) + \dots + [\xi_{n-1} - \xi_n] s_{n-1}(y) + \xi_n s_n(y) \end{aligned}$$

(What we have used is the identity $\sum_{i=1}^n a_i b_i = \sum_{i=1}^{n-1} [a_i - a_{i+1}] \sum_{j=1}^i b_j + a_n \sum_{j=1}^n b_j$; this discrete analogy of integration by parts is called *Abel transformation*). Similarly, $s_k(x) = x_1 + \dots + x_k$, whence

$$\xi^T x = [\xi_1 - \xi_2] s_1(x) + [\xi_2 - \xi_3] s_2(x) + \dots + [\xi_{n-1} - \xi_n] s_{n-1}(x) + \xi_n s_n(x).$$

Comparing the resulting expressions for $\xi^T y$ and $\xi^T x$ and taking into account that $\xi_k - \xi_{k+1} \geq 0$, $s_k(y) \leq s_k(x)$ and $s_n(y) = s_n(x)$, we conclude that $\xi^T y \leq \xi^T x$. Since $x \in X$, the latter inequality contradicts (!). We have arrived at a desired contradiction. \square

Part II

Classical Algorithms of Linear Optimization: the Simplex Method

Lecture 4

Simplex Method

In this lecture, we focus on historically the first algorithm for solving LO programs — the famous Simplex method invented by George Dantzig in late 1940's. The importance of this invention can hardly be overestimated: the algorithm turned out to be extremely successful in actual computations and for over than 4 decades was *the* working horse of LO. Today we have in our disposal also other, theoretically more advantageous (as well as better suited for many practical applications) LO algorithms; nevertheless, the Simplex method still remains indispensable in numerous applications.

As nearly all computational methods, the Simplex method is not a *single* well-defined algorithm; it is rather a common name for a *family* of algorithms of common structure. In our course, we will focus on the most basic members of this family — the *Primal* and the *Dual Simplex methods*. These methods heavily exploit the specific geometry of LO. The informal “high level” description of the Simplex method is quite transparent and natural. Assume that the feasible set of an LO program is nonempty and does not contain lines. From the theory developed in lecture 2 it then follows that if the program is feasible, its optimal solution, if any, can be found among the finitely many candidates – the vertices of the feasible set. The Simplex method moves along the vertices according to the following scheme (see figure 4.1):

- staying at a current vertex v , the method checks whether there is an edge — a one-dimensional face of the feasible set — which contains v and is an *improving* one, that is, moving from v along this edge, the objective improves (increases when speaking of a maximization problem and decreases when the problem is a minimization one). There are three possibilities:

- an improving edge does not exist. It can be proved that in this case the vertex is the optimal solution;
- there exists an improving edge, which, geometrically, is a ray, that is, moving from v along this edge, we never leave the feasible set. In this case the problem clearly is unbounded;
- there exists an improving edge which is a nontrivial segment and thus has two vertices which, being vertices of a face of the feasible set, are vertices of this set itself (Proposition 2.3.3). One of these vertices is v ; denoting the other vertex by v^+ and taking into account that the edge is an improving one, the value of the objective at v^+ is better than its value at v . The Simplex method moves from v to v^+ , and proceeds from this point as from v .

Since there are only finitely many vertices and the method before termination strictly improves the objective and thus cannot visit the same vertex twice, it in finitely many steps either finds

Figure 4.1: Geometry of Simplex Method. The objective to be maximized is the ordinate (“height”). Left: method starts from vertex S and ascends to vertex F where an improving ray is discovered, meaning that the problem is unbounded. Right: method starts from vertex S and ascends to the optimal vertex F.

an improving ray and terminates with the (correct) claim that the program is unbounded, or arrives at a vertex which does not admit an improving edge and thus is optimal. The essence of the matter is in the fact that there are relatively simple, quite transparent and fully algorithmic algebraic tools which, modulo “degenerate cases” (which need a special treatment and never occur when the problem is “in general position”), make it easy to implement the above strategy, that is, to find, given a vertex, an improving edge, or to detect correctly that no one exists.

Note that the outlined “finiteness” of the Simplex method by itself does not promise much — if finiteness were the only goal, why not to use the Fourier-Motzkin elimination scheme (see p. 26)? The only upper bound on the number of steps of the Simplex method (i.e., the number of vertices visited before termination) given by the proof of method’s finiteness is that the total number of steps is bounded by the total number of vertices, and the latter can be astronomically large: the polytope as simple as the n -dimensional box has 2^n vertices! It is a kind of miracle (which, in our opinion, still does not have a good explanation) that “in reality” the method visits a negligible part of all vertices (empirically speaking, just a moderate multiple of the number of equality constraints in the standard form of the program) and is a surprisingly successful algorithm capable to solve routinely in reasonable time “real world” LO programs with tens and hundreds of thousands of variables and constraints.

4.1 Simplex Method: Preliminaries

Primal and Dual Simplex methods (PSM and DSM for short) are directly applicable to an LO program in the standard form

$$\text{Opt}(P) = \max_{x \in \mathbf{R}^n} \{c^T x : x \in X = \{x : Ax = b, x \geq 0\}\}, \quad A = [a_1^T; \dots; a_m^T]; \quad (4.1.1)$$

as we remember from lecture 1, every LO program can be straightforwardly converted to this form.

Assumption. From now on, we make the following

Assumption: *The system of linear constraints $Ax = b$ in (4.1.1) is feasible, and the equations in this system are linearly independent, so that the rank of A is equal to the number m of rows in A .*

Note that to check the solvability of a system of linear equations $Ax = b$ is a simple Linear Algebra task; if the system is not feasible, so is the LO program (4.1.1), and its processing is therefore complete. If the system $Ax = b$ is solvable, then the solution set remains intact when we eliminate from the system, one at a time, equations which are linear combinations of the remaining equations until a system with linearly independent equations is built; this reduction of redundant linear equations again is a simple Linear Algebra task. We see that our Assumption (which by default acts everywhere in the sequel) in fact does not restrict generality.

4.2 Geometry of an LO Program in the Standard Form

Our next step is to understand how our results on the geometry of a general type LO program should be specialized when the program is in the standard form. We start with building up the problem dual to (4.1.1).

4.2.1 The Dual of an LO Program in the Standard Form

The dual to (4.1.1) reads

$$\text{Opt}(D) = \min_{\lambda} \{b^T \lambda : c - A^T \lambda \leq 0\}. \quad (4.2.1)$$

The optimality conditions read (see Proposition 3.3.1):

Proposition 4.2.1 *A feasible solution x to (4.1.1) is optimal iff there exists vector of Lagrange multipliers $\lambda \in \mathbf{R}^m$ such that $c - A^T \lambda \leq 0$ and*

$$x_j(c - A^T \lambda)_j = 0, \quad 1 \leq j \leq n \quad [\text{complementary slackness}]$$

If λ satisfies these requirements w.r.t. some feasible solution x to (4.1.1), then λ is an optimal solution to the dual problem (4.2.1).

Note that when replacing the original objective $c^T x$ in (4.1.1) with $[c - A^T \lambda]^T x$, on the feasible set of the program the objective is changed by a constant (specifically, by $-\lambda^T b$), and the primal problem remains intact. In LO terminology, such an equivalent modification $c \mapsto c - A^T \lambda$ of the primal objective is called *passing to reduced costs*.¹ Proposition 4.2.1 says that a primal feasible solution x is optimal iff there exist reduced costs $c - A^T \lambda$ which “make optimality evident” – all the reduced costs are nonpositive and complementary slackness w.r.t. x takes place, so that the new objective is nonpositive everywhere on the nonnegative orthant, while being zero at x due to the complementary slackness; thus, x maximizes the new objective on the *entire nonnegative orthant*, not speaking about maximizing the new (and thus the old) objective on the primal feasible set.

¹This terminology fits a *minimization* LO in the standard form, where c_i can be interpreted as costs. In our maximization setting of the primal problem, the name “reduced profits” would be more to the point, but we prefer to stick to the standard terminology.

4.2.2 Basic and Basic Feasible Solutions

Now it is time to investigate the vertices of the primal feasible set $X = \{x \in \mathbf{R}^n : x \geq 0 : Ax = b\}$ and the dual feasible set $\Lambda = \{\lambda \in \mathbf{R}^m : c - A^T \lambda \leq 0\}$. Note X does not contain lines (as a part of the nonnegative orthant \mathbf{R}_+^n which does not contain lines), and Λ does not contain lines due to the fact that A is of rank m , that is, A^T has trivial kernel.

We call a collection $I = \{i_1, \dots, i_m\}$ of m distinct indices from the index set $\{1, \dots, n\}$ a *basis* of (4.1.1), if the corresponding columns A_{i_1}, \dots, A_{i_m} of A are linearly independent (and thus form a linear basis in the space \mathbf{R}^m to which they belong). Since A is of rank m , bases do exist. If I is a basis, we can partition every vector $x \in \mathbf{R}^n$ into its m -dimensional *basic part* x_I comprised of entries with indices from I and its *non-basic part* $x_{\bar{I}}$ comprised of all remaining entries; we shall denote this partition as $x = (x_I, x_{\bar{I}})$. We can similarly partition the matrix A : $A = (A_I, A_{\bar{I}})$, where A_I is the $m \times m$ matrix comprised of the columns of A with indices from I , and $A_{\bar{I}}$ is comprised of all remaining columns of A . With these partitions, A_I is an $m \times m$ *nonsingular* matrix, and the system of linear constraints in (4.1.1) can be written down as

$$\begin{aligned} A_I x_I + A_{\bar{I}} x_{\bar{I}} &= b \\ \Leftrightarrow x_I + [A_I]^{-1} A_{\bar{I}} x_{\bar{I}} &= [A_I]^{-1} b. \end{aligned} \quad (4.2.2)$$

We can now satisfy the primal equality constraints by setting $x_{\bar{I}} = 0$ and $x_I = [A_I]^{-1} b$, thus arriving at a *basic primal solution*

$$x^I = (x_I = [A_I]^{-1} b, x_{\bar{I}} = 0)$$

associated with basis I ; this solution satisfies the primal equality constraints, but not necessarily is feasible for the primal problem; it is primal feasible iff $x_I \geq 0$.

Similarly, given a basis I , we can try to find a dual solution λ which makes the dual inequality constraints with indices from I active, that is, is such that

$$(A^T \lambda - c)_i = 0, i \in I.$$

The matrix of coefficients in this system of m linear equations in m variables λ is A_I^T , so that the system has a unique solution

$$\lambda^I = [A_I]^{-T} c_I; \quad [B^{-T} = [B^{-1}]^T]$$

λ^I is called the *basic dual solution associated with the basis I* . This solution is not necessarily feasible for the dual problem; it is feasible iff the corresponding vector of reduced costs is nonpositive:

$$c - A^T [A_I]^{-T} c_I \leq 0.$$

Note that by construction all basic components in this vector are zeros.

The role of bases in our context stems from the following simple

Proposition 4.2.2 (i) *Let v be a feasible solution to the primal program (4.1.1). v is a vertex of the primal feasible set X iff $v = x^I$ for some basis I .*

Equivalently: vertices of X are exactly the feasible primal basic solutions.

(ii) *Let λ be a feasible solution to the dual program (4.2.1). λ is a vertex of the dual feasible set Λ iff $\lambda = \lambda^I$ for some basis I .*

Equivalently: vertices of Λ are exactly the feasible dual basic solutions.

Proof is immediate. (i): By algebraic characterization of vertices (Proposition 2.3.2), a point v from a polyhedral set $X \subset \mathbf{R}^n$ is a vertex iff among the equality/inequality constraints defining the set and active at v (i.e., satisfied at v as equalities) there are n linearly independent (i.e., with linearly independent vectors of coefficients). In our case this reads as follows: a primal feasible solution v is a vertex of X iff adding to the constraints $Ax = b$ all inequality constraints $x_j \geq 0$ which are active at v (i.e., $v_j = 0$), we get a system of linear equations which contains n linearly independent equations. Now let v be a vertex, let $J = \{j : v_j = 0\}$, and let $n - k$ be the cardinality of J . Augmenting A by $n - k$ rows e_j^T , $j \in J$, we should get a matrix of rank n which looks as follows (w.l.o.g. we have assumed that $J = \{k + 1, k + 2, \dots, n\}$):

$$\left[\begin{array}{c|c} A_1, A_2, \dots, A_k & A_{k+1}, \dots, A_n \\ \hline & I_{n-k} \end{array} \right] \quad (*)$$

(blank spaces are filled with zeros, I_{n-k} is the unit $(n - k) \times (n - k)$ matrix). Since the matrix has n columns and is of rank n , the columns should be linearly independent, which is possible iff the columns of A with indices not in J (the columns A_1, \dots, A_k in our illustration) are linearly independent. In other words, the k columns of A with indices corresponding to the nonzero entries of v are linearly independent. Since the columns of A are of the dimension m , we conclude that $k \leq m$; and since $\text{Rank}(A) = m$, we can augment the k columns we have found with $m - k$ other columns of A to get a collection of m linearly independent columns. Denoting by I the set of indices of these m columns, we get a basis of our program, and by construction $v_{\bar{I}} = 0$. Since $Av = b$, we conclude that $v_I = [A_I]^{-1}b$, that is, $v = x^I$. We have proved part (i) of Proposition in the “only if” direction. The proof in the “if” direction is even easier: if v is primal feasible and $v = x^I$ for certain basis I , then the system of primal constraints $Ax = b$, $x_j = 0, j \in \bar{I}$ which are active at v is comprised of n linearly independent equations (check it by assuming that $I = \{1, \dots, m\}$ and by looking at the analogy of $(*)$), and thus v is a vertex of the primal feasible set X by the algebraic characterization of vertices.

(ii): The proof is completely similar to the one of part (i). Assume that $\bar{\lambda}$ is a vertex of Λ . By algebraic characterization of vertices, among the inequalities $[A^T \lambda - c]_i \leq 0$, $1 \leq i \leq n$, which are satisfied at $\bar{\lambda}$ as equalities, there are $m = \dim \lambda$ with linearly independent vectors of coefficients, let their indices be i_1, \dots, i_m . In other words, the columns A_{i_1}, \dots, A_{i_m} of A (which are nothing but the vectors of coefficients in question) are linearly independent and $A_{i_\ell}^T \bar{\lambda} = c_{i_\ell}$, $\ell = 1, \dots, m$. We see that $I = \{i_1, \dots, i_m\}$ is a basis and $\bar{\lambda} = \lambda^I$. Vice versa, if I is a basis and λ^I is dual feasible, then λ^I is a feasible dual solution which makes equalities m linearly independent constraints defining Λ , specifically, the constraints $c_j - A_j^T \lambda \leq 0$ with indices $j \in I$. Applying algebraic characterization of vertices, we see that λ^I is a vertex of Λ . \square

Some remarks are in order.

A. Proposition 4.2.2 suggests the following conceptual scheme for enumerating the vertices of the feasible set X of the program (4.1.1): we look one by one at all m -element subsets I of the index set $\{1, \dots, N\}$ and skip those which are not bases. When I is a basis, we find the (unique) solution to the system $Ax = b$ with the zero non-basic part (“primal basic solution” in the LO terminology), that is, the solution $x^I = (x_I = [A_I]^{-1}b, x_{\bar{I}} = 0)$. If x_I is nonnegative, we get a vertex of the primal feasible set (“primal basic feasible solution” in the LO terminology). In this fashion, we get all the vertices of X , if any. Similar process can be used to enumerate the vertices of the dual feasible set; now these are exactly the dual basic solutions λ^I which happen to be dual feasible.

B. Pay attention to the fact that while every vertex v of X is a primal basic feasible solution, the corresponding basis not always is uniquely defined by the vertex. This basis definitely is unique, if the vertex is *nondegenerate*, that is, possesses exactly m nonzero (and thus positive) entries. In this case the basis which makes the vertex a primal basic feasible solution is comprised of indices of the m nonzero entries in the vertex. A degenerate – with less than m positive entries – vertex v can be defined by many different bases. To give an extreme example, consider the case of $b = 0$. In this case, X is a pointed cone and as such has exactly one vertex – the origin; but when $b = 0$, the origin is the primal basic feasible solution for every basis of the program, and there could be astronomically many of them.

Similarly, every vertex of the dual feasible set is a dual basic feasible solution, but a particular vertex λ of Λ can be associated with more than one basis. It may happen only when the vertex λ is *degenerate*, meaning that the number of zero entries in the corresponding vector of reduced costs $c - A^T \lambda$ is $> m$. If the vertex is nondegenerate — there are exactly m zero entries in the associated with λ vector of reduced costs — there exists exactly one basis I such that $\lambda = \lambda^I$, namely, the basis comprised of indices of the m zero entries in $c - A^T \lambda$.

Potential degeneracy (presence of degenerate vertices) of a LO program needs a special (as we shall see, not too difficult) treatment. Speaking about “general” LO programs of given sizes m, n , degeneracy (presence of at least one degenerate primal and/or dual basic feasible solution) is a “rare phenomenon” — the data of degenerate programs form a set of Lebesgue measure zero in the space \mathbf{R}^{m+n+mn} of data of all programs of these sizes. In “general position,” an LO program is nondegenerate, and every subset I of the index set $\{1, \dots, n\}$ is a basis. Nevertheless, there are important special classes of LOs where a significant part of the data are “hard zeros” (coming from problem’s structure), and in these cases degeneracy can be typical.

C. An important point is that given a primal basic feasible solution x^I , we can try to certify its optimality by building dual basic solution λ^I associated with the same basis. Observing that by construction x^I and λ^I satisfy the complementary slackness condition $x_j^I [c - A^T \lambda^I]_j = 0$ for all j (indeed, by construction the first factor can be nonzero only for $j \in I$, and the second — only for $j \notin I$), we see that *if λ^I happens to be dual feasible, x^I and λ^I are optimal solutions to the respective problems*. By exactly the same token, given a dual basic feasible solution λ^I , we can try to certify its dual optimality by building the primal basic solution x^I ; *if it happens to be primal feasible, x^I and λ^I again are optimal solutions to the respective problems*.

D. The strategy implemented in Simplex method follows the recommendations of the previous item. Specifically,

- the *Primal Simplex method* generates subsequent primal basic feasible solutions, improving at every step (strictly, if the current solution is nondegenerate) the primal objective, and augments this process by building associated dual basic solutions until either unboundedness of the primal problem is detected, or a *feasible* dual basic solution is met, thus certifying optimality of the current primal and dual basic feasible solutions;
- the *Dual Simplex method* generates subsequent dual basic feasible solutions, improving at every step (strictly, if the current solution is nondegenerate) the dual objective, and augments this process by building associated primal basic solutions until either unboundedness of the dual problem is detected, or a *feasible* primal basic solution is met, thus certifying optimality of the current primal and dual basic feasible solutions.

In both cases, the finiteness of the method in the nondegenerate case follows from the fact that the corresponding objective strictly improves from step to step, which makes it impossible to visit twice the same primal (in the Primal Simplex Method) or dual (in the Dual Simplex Method) vertex; since the number of vertices is finite, the method *must* terminate after finitely

many steps.

E. Finally, we make the following observation closely related to detecting unboundedness:

Observation 4.2.1 *Let I be a basis.*

(i) *Assume that $j \notin I$ and $w \in \mathbf{R}^n$ is a nonzero vector such that $w \geq 0$, $w_j = 0$ when $j \notin I \cup \{j\}$ and $Aw = 0$. Then w is the direction of an extreme ray of the recessive cone of the primal feasible domain $X = \{x \in \mathbf{R}^n : x \geq 0, Ax = b\}$ of (4.1.1).*

(ii) *Assume that $\mu \in \mathbf{R}^m$ is a nonzero vector such that $A^T \mu \geq 0$ and $(A^T \mu)_j = 0$ for all but one indices $j \in I$. Then μ is the direction of an extreme ray of the recessive cone of the dual feasible domain $\Lambda = \{\lambda \in \mathbf{R}^m : c - A^T \lambda \leq 0\}$ of (4.1.1).*

Indeed, the recessive cone of X is $\text{Rec}(X) = \{x \in \mathbf{R}^n : x \geq 0, Ax = 0\}$. w clearly belongs to this cone and makes equalities $n - 1$ of the homogeneous constraints defining $\text{Rec}(X)$, specifically, m constraints $a_i^T x = 0$, $i = 1, \dots, m$ and $n - m - 1$ constraints $e_j^T x = 0$, $j \notin I \cup \{j\}$. Since the rows of A_I are linearly independent, the $n - 1$ vectors $a_1, \dots, a_m, \{e_j\}_{j \notin I \cup \{j\}}$ are linearly independent, and (i) follows from Proposition 2.3.9.(i).

Similarly, the recessive cone of Λ is $\text{Rec}(\Lambda) = \{\lambda \in \mathbf{R}^m : A^T \lambda \geq 0\}$; μ clearly belongs to this cone and makes equalities $m - 1$ among the m homogeneous linear equations $A_j^T \lambda \geq 0$, $j \in I$, participating in the description of the cone. Since the vectors A_j , $j \in I$, are linearly independent, (ii) follows from Proposition 2.3.9.(i). \square

4.3 Simplex Method

4.3.1 Primal Simplex Method

We are ready to present the PSM. In what follows, italicized paragraphs constitute the description of the method, while the usual text between these paragraphs contains explanations.

In the description to follow, we assume that the program (4.1.1) is feasible and, moreover, we have in our disposal a starting point which is a basis associated with a primal basic feasible solution to the program.

At step t , the current basic feasible solution x^I associated with the current basis I and this basis are updated according to the following rules.

- A.** *We compute the vector $c^I = c - A^T \lambda^I$, $\lambda^I = [A_I]^{-T} c_I$, of the reduced costs associated with the basis I . If c^I is nonpositive, we terminate with the claim that x^I is an optimal solution to the primal program, and λ^I is the optimal solution to the dual program, otherwise we pass to item **B**.*
- B.** *We pick an index j – a pivot – such that the reduced cost c_j^I is positive (such an index does exist, otherwise we were not invoking **B**; the index does not belong to I , since by construction the basic reduced costs c_i^I (those with $i \in I$) are zeros). We then try to increase the variable x_j (which was zero in the solution x^I), allowing for updating the basic entries x_i , $i \in I$, in a feasible solution, and keeping the entries with indices outside of $I \cup \{j\}$ zeros. Specifically, let $x(t)$, $t \geq 0$, be given by*

$$x_i(t) = \begin{cases} 0, & i \notin I \cup \{j\} \\ t, & i = j \\ x_i^I - t([A_I]^{-1} A_j)_i, & i \in I \end{cases} \quad (4.3.1)$$

Comment: the origin of (4.3.1) is as follows. $x(t)$ is the feasible solution of the system $Ax = b$ such that $x_j(t) = t$ and $x_i(t) = 0$ when $i \notin I \cup \{j\}$. As is seen from the second relation in (4.2.2), the basic entries $x_i(t)$, $i \in I$, in $x(t)$ should be exactly as stated in (4.3.1). Note that while $x(t)$ satisfies the constraints $Ax = b$ for all $t \geq 0$, the feasibility of $x(t)$ for the program (which amounts to nonnegativity of all entries in $x(t)$) depends on what happens with the basic entries $x_i(t)$. For every $i \in I$, there are just two possibilities:

- (A): the associated quantity $([A_I]^{-1}A_j)_i$ is nonpositive. In this case, the variable $x_i(t)$ is nonnegative for every $t \geq 0$.
- (B): the associated quantity $([A_I]^{-1}A_j)_i$ is positive, in which case $x_i(t)$ is nonnegative iff $t \leq t_i := [x_i^I] \left([A_I]^{-1}A_j\right)_i^{-1}$ and becomes negative when $t > t_i$. Note that t_i is nonnegative since x_i^I is so.

We check whether (A) takes place for all basic indices i (i.e., indices from the current basis I). If it is the case, we terminate and claim that the program is unbounded. If there are basic indices for which (B) takes place, we define t^* as the minimum, over these basic indices, of the corresponding t_i 's, and set i_* equal to the basic index corresponding to this minimum:

$$t_* = \min_i \left\{ t_i := [x_i^I] \left([A_I]^{-1}A_j\right)_i^{-1} : ([A_I]^{-1}A_j)_i > 0 \right\}, \quad i_* : ([A_I]^{-1}A_j)_{i_*} > 0 \text{ \& } t_* = t_{i_*}.$$

We specify our new basis as $I^+ = [I \setminus \{i_*\}] \cup \{j\}$ (in the LO terminology: the variable x_j enters the basis, the variable x_{i_*} leaves it), our new basic feasible solution as $x^{I^+} = x(t_*)$ and pass to the next step of the method.

Several justifications and comments are in order.

I. According to the above description, a step of the PSM can lead to three outcomes as follows:

1. termination with the claim that the current primal basic feasible solution x^I is optimal; this happens when all the reduced costs c_i^I are nonpositive.
In this situation, the claim is correct due to the discussion in item **C** of section 4.2.2, see p. 148.
2. termination with the claim that the problem is unbounded; this happens when for all basic indices, (A) is the case.

In the situation in question, the claim is correct. Indeed, in this situation $x(t)$ is feasible for the primal program for all $t \geq 0$. As we remember, replacing the original objective $c^T x$ with the objective $[c^I]^T x$ reduces to adding a constant to the restriction of the objective on the primal feasible plane. Since $c_i^I = 0$ for $i \in I$, $c_j^I > 0$ (due to the origin of j) and all entries in $x(t)$ with indices not in $I \cup \{j\}$ are zeros, we have

$$[c^I]^T x(t) = \sum_{i \in I} c_i^I x_i(t) + c_j^I x_j(t) = c_j^I x_j(t) = c_j^I t \rightarrow +\infty, \quad t \rightarrow \infty,$$

whence also $c^T x(t) \rightarrow +\infty$ as $t \rightarrow \infty$, thus certifying that the problem is unbounded. Note that in the case in question the improving direction $\frac{d}{dt}x(t)$ is the direction of an extreme ray of $\text{Rec}(X)$, $X = \{x : x \geq 0, Ax = b\}$ being the feasible domain of (4.1.1), see Observation 4.2.1.

3. passing to a new step with the claims that I^+ is a basis, and $x(t_*)$ is the corresponding primal basic feasible solution.

In this situation, the claims also are correct, which can be seen as follows. From the origin of t_* and i_* it is clear, first, that $x(t^*)$ satisfies the equality constraints of the problem and is nonnegative (i.e., is a feasible solution), and, second, that $(x(t^*))_i = 0$ when $i = i_*$ and when $i \notin I \cup \{j\}$, that is, $(x(t_*))_i$ can be positive only when $i \in I^+$. Further, I^+ by construction is an m -element subset of $\{1, \dots, n\}$. Thus, all which remains to verify in order to support the claims in question is that I^+ is a basis, that is, that the m columns A_i , $i \in I^+$, of A are linearly independent. This is immediate: assuming the opposite and taking into account that the columns A_i , $i \in I \setminus \{i_*\}$ of A “inherited” from I are linearly independent, the only possibility for A_i , $i \in I^+$, to be linearly dependent is that A_j is the linear combination of these inherited columns, which amounts to the existence of a representation

$$A_j = \sum_{i=1}^n \mu_i A_i$$

with $\mu_i = 0$ whenever $i \notin I$ or $i = i_*$. But then the vector

$$y(t) = x - t\mu + te_j$$

satisfies exactly the same requirements as the vector $x(t)$: $Ay(t) = Ax = b$, all coordinates in $y(t)$, except for those with indices from $I \cup \{j\}$, are zero, and the j -th coordinate equals to t . From the explanation where $x(t)$ comes from it follows that $x(t) = y(t)$, which, in particular, implies that $(x(t))_{i_*}$ is independent of t (recall that $\mu_{i_*} = 0$). But the latter is impossible due to

$$x_{i_*}(t) = x_{i_*}^I - t([A_I]^{-1}A_j)_{i_*}$$

and the fact that $([A_I]^{-1}A_j)_{i_*} > 0$.

The bottom line is that *PSM is a well-defined procedure* – when running it, at every step we either terminate with correct claims “the current basic feasible solution is optimal” or “the problem is unbounded”, or have a possibility to make the next step, since the updated I and x^I are what they should be (a basis and the associated primal basic feasible solution) in order make the next step well defined.

II. The correctness of PSM is a good news, but by itself this news is not sufficient: we want to get an optimal solution, and not just “to run.” What is crucial in this respect, is the following

Observation 4.3.1 *SMP is a monotone process: if x^I and x^{I^+} are two consecutive primal basic feasible solutions generated by the method, then $c^T x^I \leq c^T x^{I^+}$, with the inequality being strict unless $x^I = x^{I^+}$. The latter never happens when the basic feasible solution x^I is nondegenerate.*

The verification is immediate. In the notation from the description of PSM and due to the explanations above, we have $c^T x^{I^+} - c^T x^I = [c^I]^T x^{I^+} - [c^I]^T x^I = c_j^I t^* \geq 0$, the equality being possible iff $t^* = 0$. The latter can happen only when x^I is degenerate, since otherwise $x_i^I > 0$ for all $i \in I$ and thus $t_i > 0$ for all $i \in I$ for which t_i are well defined. \square

We arrive at the following

Corollary 4.3.1 *The Primal Simplex method, initiated at a primal basic feasible solution of (4.1.1), possess the following property: if the method terminates at all, the result upon termination either is a primal basic feasible solution which is an optimal solution to the program, or is a correct claim that the problem is unbounded. In the first case, the method produces not only the primal optimal solution, but also the corresponding optimality certificate — an optimal basic solution to the dual problem. In the second case, the method produces a ray which is contained in the feasible set of the problem and is a ray along which the objective increases, so that this ray is a certificate of unboundedness. In fact, this ray is an extreme ray of the recessive cone of the primal feasible set.*

The method definitely terminates in finitely many steps, provided that the program is primal nondegenerate (i.e., all primal basic feasible solutions are so).

This result is an immediate corollary of our preceding observations. The only claim that indeed needs a comment is the one of finite termination on a nondegenerate problem. On a closest inspection, this property is immediate as well: when the problem is nondegenerate, every step before termination increases the value of the objective, implying that the method cannot visit the same vertex more than once. Since the number of vertices is finite, and method before termination moves from vertex to vertex, the number of steps before termination is finite as well. \square

4.3.2 Tableau Implementation and Example

To illustrate the Primal Simplex Method let us work out an example. In this example, we will use the so called *full tableau form* of the algorithm well suited for both thinking about the method and solving LO programs by hand (while now the latter process takes place in classrooms only, once upon a time this was how the LO programs, of course, toy ones in our today scale, were actually solved). The idea is that if I is a basis of the program of interest, then the original program is equivalent to the program

$$\max_x \{ [c^I]^T x : [A_I]^{-1} Ax = [A_I]^{-1} b \}, \quad c^I = c - A^T [A_I]^{-T} c_I \quad (*)$$

and we can keep the data of this equivalent problem, along with the current basic feasible solution x^I , in a tableau of the form

$-c_I^T x_I^I$	$[c^I]^T$
$[A_I]^{-1} b$	$[A_I]^{-1} A$

or, in more detailed form,

$-c_I^T x_I^I$	$c_1^I \dots c_n^I$
$x_{i_1}^I$	$[[A_I]^{-1} A]^1$
\vdots	\dots
$x_{i_m}^I$	$[[A_I]^{-1} A]^m$

where $I = \{i_1, \dots, i_m\}$ and $[B]^s$ stands for s -th row of a matrix B . It should be stressed that what we keep in the tableau, are the *values* of the corresponding expressions, not the expressions themselves. It is convenient to count the rows and the columns of a tableau starting from 0; thus, the zeroth row contains the *minus* value of the objective at the current basic feasible solution

augmented by the reduced costs; rows 1,2,... are labelled by the current basic variables and contain the entries of the vector $[A_I]^{-1}b$ augmented by the entries of the corresponding rows in $[A_I]^{-1}A$. Since $(*)$ is equivalent to the original problem, we can think about every iteration as about *the very first iteration of the method as applied to $(*)$* , and our goal is to update the tableau representing the current equivalent reformulation $(*)$ of the problem of interest into the tableau representing the next equivalent reformulation of the problem of interest.

Now let us work out a numerical example ([3, Example 3.5]). The initial program is

$$\begin{array}{ll} \max & 10x_1 + 12x_2 + 12x_3 \\ \text{subject to} & \\ & x_1 + 2x_2 + 2x_3 \leq 20 \\ & 2x_1 + x_2 + 2x_3 \leq 20 \\ & 2x_1 + 2x_2 + x_3 \leq 20 \\ & x_1, x_2, x_3 \geq 0 \end{array}$$

We introduce slack variables to convert the problem to the standard form, thus arriving at the program

$$\begin{array}{ll} \max & 10x_1 + 12x_2 + 12x_3 \\ \text{subject to} & \\ & x_1 + 2x_2 + 2x_3 + x_4 = 20 \\ & 2x_1 + x_2 + 2x_3 + x_5 = 20 \\ & 2x_1 + 2x_2 + x_3 + x_6 = 20 \\ & x_1, \dots, x_6 \geq 0 \end{array}$$

which allows us to point out a starting basis $I = \{4, 5, 6\}$ and the starting basic feasible solution x^I with nonzero entries $x_4 = x_5 = x_6 = 20$. The first tableau is

	x_1	x_2	x_3	x_4	x_5	x_6
0	10	12	12	0	0	0
$x_4 = 20$	1	2	2	1	0	0
$x_5 = 20$	2	1	2	0	1	0
$x_6 = 20$	2	2	1	0	0	1

The reduced cost of x_1 is positive; let this be the variable entering the basis. When trying to replace $x_1 = 0$ with $x_1 = t \geq 0$, keeping x_2 and x_3 zeros, the basic variables x_4, x_5, x_6 start to change: $x_4(t) = 20 - 1 \cdot t$, $x_5(t) = 20 - 2 \cdot t$, $x_6(t) = 20 - 2 \cdot t$. The largest t which keeps all there variables nonnegative, is $t^* = 20/2 = 10$, and it is clear where this value comes from: this is just the *minimum*, over all rows in the tableau corresponding to A and containing positive entries in the pivoting column (in our case, the column of x_1), of the ratios “value of the basic variable labelling the row” (shown in the zeroth column of the tableau) to the entry in the intersection of the row and the pivoting column:

$$t_* = \min \left[\frac{20}{1}, \frac{20}{2}, \frac{20}{2} \right]$$

In fact, the minimum of this ratio is achieved simultaneously in two rows, and this is in our will to decide which one of the current basic variables, x_5 or x_6 , is leaving the basis. Let us say this is x_5 ; thus, at the first iteration x_1 enters the basis, and x_5 leaves it. It remains to update the tableau, that is, to replace the rows in the tableau representing the equality constraints by their

linear combinations in order to get the unit matrix (which in the initial tableau is in the columns 4,5,6) in the rows 1, 4, 6 corresponding to our new basis, and augment this transformation by updating the column of basic variables and the “zeroth row” containing the optimal value and the reduced costs. The rules for this updating are as follows (check their validity!):

- we mark somehow the *pivoting element* – the element in the pivoting column and the row of the basic variable which leaves the basis (in our tableau, it is underlined)
- we divide the entire *pivoting row* (i.e., the row of the pivoting element) by the pivoting element, thus making the pivoting element equal to 1; note that in the “basic variables” part of the pivoting row we get exactly t^* , that is, the would-be value of the variable (x_1) which enters the basis; we update accordingly the “basic variable label” of this row, thus arriving at the intermediate tableau

	x_1	x_2	x_3	x_4	x_5	x_6
0	10	12	12	0	0	0
$x_4 = 20$	1	2	2	1	0	0
$x_1 = 10$	<u>1</u>	0.5	1	0	0.5	0
$x_6 = 20$	2	2	1	0	0	1

- finally, we subtract from every non-pivoting row of the intermediate tableau a multiple of the updated pivoting row, the coefficient of the multiple being the entry in the pivoting column of the non-pivoting row we are processing; as a result, all entries in the pivoting column, aside of the one of the pivoting row, become zeros. What we get is nothing but our new tableau:

	x_1	x_2	x_3	x_4	x_5	x_6
-100	0	7	2	0	-5	0
$x_4 = 10$	0	1.5	<u>1</u>	1	-0.5	0
$x_1 = 10$	1	0.5	1	0	0.5	0
$x_6 = 0$	0	1	-1	0	-1	1

Now we process the new tableau exactly in the same fashion as the initial one:

- there are two variables with positive reduced cost — x_2 and x_3 ; we choose one of them, say, x_3 , as the variable entering the basis, so that the pivoting column is the column of x_3 ;
- we divide the values of basic variables shown in the tableau by the corresponding values in the pivoting column, *skipping the divisions by nonpositive entries of the latter column*; the results are $\frac{10}{1} = 10$ in the first row and $\frac{10}{1} = 10$ in the second row. We then choose the element in the pivoting row corresponding to the smallest ratio as the pivoting element, and its row — as the pivoting row. In our example, we can choose both the first and the second row as the pivoting one; let our choice be the first row.
- we now mark the pivoting element, divide by it the pivoting row (with our numbers, this does not change the pivoting row) and replace the basic variable label x_5 in this row (x_5 is the variable which leaves the basis) with the label x_3 (this is the variable which enters the basis, so that the new basis is 3, 1, 6)
- finally, we subtract from all non-pivoting rows of the tableau the multiples of the (already

updated) pivoting row to zero entries in the pivoting column, thus arriving at the new tableau

	x_1	x_2	x_3	x_4	x_5	x_6
-120	0	4	-2	0	-4	0
$x_3 = 10$	0	1.5	1	1	-0.5	0
$x_1 = 0$	1	-1	0	-1	1	0
$x_6 = 10$	0	<u>2.5</u>	0	1	-1.5	1

In the zeroth row of the new tableau, there is only one positive reduced cost, the one of x_2 , meaning that x_2 should enter the basis. The pivoting row corresponds now to the minimum of the ratios $\frac{10}{1.5}$ (row of x_3) and $\frac{10}{2.5}$ (row of x_6), that is, the pivoting row is the one of x_6 , the pivoting element is 2.5, and the variable leaving the basis is x_6 (so that the new basis is 1,2,3). We proceed by

— dividing the pivoting row by the pivoting element and updating the basic variable mark in the row from x_6 (this variable leaves the basis) to x_2 (this is the variable which enters the basis). The updated pivoting row is

$$x_2 = 4 \quad \left| \quad 0 \quad 1 \quad 0 \quad 0.4 \quad -0.6 \quad 0.4 \right|$$

We then subtract from all non-pivoting rows of the tableau multiples of the just transformed pivoting row to zero the corresponding entries in the pivoting column. The result is the new tableau

	x_1	x_2	x_3	x_4	x_5	x_6
-136	0	0	0	-3.6	-1.6	-1.6
$x_3 = 4$	0	0	1	0.4	0.4	-0.6
$x_1 = 4$	1	0	0	-0.6	0.4	0.4
$x_2 = 4$	0	1	0	0.4	-0.6	0.4

In this tableau, all reduced costs are nonpositive, meaning that we have built the optimal solution to the problem. This optimal solution is

$$x_1 = x_2 = x_3 = 4, x_5 = x_6 = x_7 = 0$$

(this is said by the column of the values of basic variables), the optimal value is 136 (*minus* the number in very first cell of the zeroth row of the tableau) and the *minus* optimal dual slack – the vector of the reduced costs $c - A^T \lambda_*$ corresponding to the dual optimal solution λ_* is the vector $[0; 0; 0; -3.6; -1; 6; -1; 6]$ the transpose of which we see in the “reduced costs” part of the zeroth row of the final tableau.

Remark. A careful reader should have noticed at this point a slight discrepancy between what was promised in the beginning of the “tableau story” and what we actually see in the above tableaus, starting from the second of them. Specifically, the matrices we see in the rows 1,2,..., m of the tableaus are not exactly the matrices $[[A_I]^{-1}b, [A_I]^{-1}A]$ (were it so, we would see in the basic columns of the tableaus the unit $n \times n$ matrix, while what we actually see is obtained from the unit matrix by permuting rows). This is due to the fact (absolutely irrelevant in our context) that what we actually keep in the tableaus is obtained from matrices $[[A_I]^{-1}b, [A_I]^{-1}A]$ by permuting rows. This is also seen from the fact that the basic variables labelling the rows are not ordered. Permuting the rows 1, ..., m to make the labels ordered would result in the tableau matrices being *exactly* of the form $[[A_I]^{-1}b, [A_I]^{-1}A]$, but there is absolutely no necessity in this reordering.

4.3.3 Preventing Cycling

We have seen that the Primal Simplex Method, *if it terminates*, solves the problem it is applied to, and that the method definitely terminates when the program is primal nondegenerate (i.e., all primal basic feasible solutions have exactly m nonzero entries). The degenerate case needs a special treatment, since here, without additional precautions, the method indeed can “loop forever”, staying at the same degenerate and nonoptimal basic feasible solution; all that changes from step to step, are only the bases specifying this solution, but not the solution itself. Fortunately it is easy to prevent cycling by applying *lexicographic pivoting rule* which we are about to explain.

Lexicographic order. We start with the notion of the *lexicographic order* on \mathbf{R}^n . Specifically, we say that vector $u \in \mathbf{R}^n$ *lexicographically dominates* vector $v \in \mathbf{R}^n$ (notation: $u \geq_L v$) if either $u = v$, or the first nonzero entry in the difference $u - v$ is positive. We write $u >_L v$, when $u \geq_L v$ and $u \neq v$, same as write $v \leq_L u$ and $v <_L u$ as equivalents of $u \geq_L v$, $u >_L v$, respectively. For example, here is a sample of valid lexicographic inequalities:

$$[1; 2; 3] \leq_L [1; 2; 4]; [1; 2; 3] <_L [2; -1; 100]; [2; -1; 10] >_L [2; -1; 9].$$

Note that the lexicographic inequalities follow the same arithmetic as the usual arithmetic inequalities $\leq, <$ between reals and the coordinate-wise inequalities $u \leq v$, $u < v$ for vectors, e.g.,

$$\left. \begin{aligned} u &\leq_L u \text{ [reflexivity]} \\ (u &\geq_L v) \ \& \ (v \leq_L u) \Rightarrow u = v \text{ [anti-symmetry]} \\ (u &\leq_L v) \ \& \ (v \leq_L w) \Rightarrow u \leq_L w \text{ [transitivity]} \\ u &<_L v, \mathbf{R} \ni \lambda > 0 \Rightarrow \lambda u <_L \lambda v; \\ u &\leq_L v, u' <_L v' \Rightarrow u + u' <_L v + v' \end{aligned} \right\} \text{ [compatibility with linear operations]}$$

Exactly as in the case of arithmetic inequalities with reals, and in contrast to what happens to the coordinate-wise vector inequality \leq between vectors, the lexicographic order is *complete* – for every pair u, v of vectors of the same dimension, we have either $u <_L v$, or $u = v$, or $u >_L v$, and these three possibilities are mutually exclusive.

Lexicographic pivoting rule. This is a specific rule for choosing a pivoting element in the Primal Simplex Method in the case when such a choice is necessary (that is, the current tableau contains positive reduced costs). The rule is as follows:

(L) Given the current tableau which contains positive reduced costs c_j^I , choose as the index of the pivoting column a j such that $c_j^I > 0$.

Denote by u_i the entry of the pivoting column in row i , $i = 1, \dots, m$, and let some of u_i be positive (recall that otherwise the PSM terminates with the (correct) claim that the problem is unbounded). Normalize every row i with $u_i > 0$ by dividing all its entries, including those in the zeroth column, by u_i , and choose among the resulting $(n + 1)$ -dimensional row vectors the smallest w.r.t the lexicographic order, let its index be i_* . The pivoting row is the one with index i_* , so that the basic variable (the one which labels the row) leaves the basis, while the variable x_j enters the basis.

Observe that at a non-terminal iteration, the outlined rule defines i_* in a unique fashion, and that it is compatible with the construction of the Simplex method, that is, i_* corresponds to the minimal, over the rows with $u_i > 0$, ratio of the zeroth entry in the row to the element of the row in the pivoting column (in the description of an iteration of PSM, these ratios were called t_i , and their minimum was called t^*).

Indeed, taking into account that the lexicographic order is complete, in order to prove that i_* is uniquely defined it suffices to verify that the normalizations of the rows $1, \dots, m$ in the tableau are distinct from each other, or, which is the same, that before normalization, these rows were not proportional to each other. The latter is evident (look what happens in the columns indexed by basic variables). Now, the zeroth entries of the normalized rows i with $u_i > 0$ are exactly the quantities t_i from the description of a simplex iteration, and by definition of the lexicographic order, the lexicographically minimal among these normalized rows corresponds to the smallest value t_* of t_i 's, as claimed.

Thus, in the context of PSM, the lexicographic pivoting rule is completely legitimate. Its role stems from the following

Theorem 4.3.1 *Let the Primal Simplex Method with pivoting rule (L) be initialized by a primal basic feasible solution, and, in addition, let all rows in the initial tableau, except for the zeroth row, be lexicographically positive. Then*

- (i) *Every row in the tableau, except for the zeroth one, remains lexicographically positive at all non-terminal iterations of the algorithm;*
- (ii) *When passing from the current tableau to the next one, if any, the vector of reduced costs strictly lexicographically decreases;*
- (iii) *The method terminates in finitely many iterations.*

Proof. (i): It suffices to prove that if all rows with indices $i = 1, 2, \dots, m$ in the current tableau are lexicographically positive and the next tableau does exist (i.e., the method does not terminate at the iteration in question), then every row i , $i = 1, \dots, m$, in the next tableau also will be lexicographically positive. Let the index of the pivoting row be ℓ , and the index of the pivoting column be j . Denoting u_1, \dots, u_m the entries in the pivoting column and i -th row, and invoking the lexicographic pivoting rule, we have

$$u_\ell > 0 \ \& \ \frac{\ell\text{th row}}{u_\ell} <_L \frac{i\text{th row}}{u_i} \ \forall (i : i \neq \ell \ \& \ u_i > 0).$$

let r_i be i th row in the current tableau, and r_i^+ be the i th row in the next tableau, $1 \leq i \leq m$. Then by description of the method:

- when $i = \ell$, $r_i^+ = u_\ell^{-1} r_\ell$, so that $r_\ell^+ >_L 0$ due to $r_\ell >_L 0$ (recall that we are under the assumption that $r_i >_L 0$ for all $1 \leq i \leq m$);
- when $i \neq \ell$ and $u_i \leq 0$, we have $r_i^+ = r_i - \frac{u_i}{u_\ell} r_\ell >_L 0$ due to $r_i >_L 0$, $r_\ell >_L 0$ and $-u_i/u_\ell \geq 0$;
- when $i \neq \ell$ and $u_i > 0$, we have $r_i^+ = r_i - \frac{u_i}{u_\ell} r_\ell^+$, or

$$\frac{1}{u_i} r_i^+ = \frac{1}{u_i} r_i - \frac{1}{u_\ell} r_\ell.$$

By the lexicographic pivoting rule, the ℓ th normalized row $\frac{1}{u_\ell} r_\ell$ is strictly less lexicographically than the i th normalized row $\frac{1}{u_i} r_i$ (due to $u_i > 0$ and $i \neq \ell$), whence $\frac{1}{u_i} r_i^+ >_L 0$, whence $r_i^+ >_L 0$ as well.

(i) is proved.

(ii): By the description of the method, the reduced costs c^I and c^{I+} in the current and the next tableaus are linked by the relation

$$c^{I+} = c^I - \frac{c_j^I}{u_\ell} [r_\ell]^T.$$

since $c_j^I > 0$ and $r_\ell >_L 0$, we have $c^{I+} <_L c^I$. (ii) is proved.

(iii) The iterations of the Simplex Method prior to termination, if the latter indeed happens, can be split into consecutive *phases* in such a way that the primal basic feasible solutions associated with the iterations from a particular phase are equal to each other and are distinct from the primal basic feasible solutions associated with the iterations of the next phase, if any. When passing from a phase to the next one, the primal basic feasible solution changes, and thus the primal objective strictly increases; it follows that distinct phases are associated with distinct primal basic feasible solutions, and since there are finitely many of these solutions, the number of phases is finite. It follows that in order to prove that the method is finite, it suffices to verify that a particular phase cannot last forever. But this is evident: since there are finitely many bases, in an infinite phase certain basis would be visited more than once. The latter is impossible, since the reduced costs, by construction, are uniquely defined by the corresponding basis, on one hand, and, by (ii) strongly lexicographically decrease along the iterations, on the other hand, so that the same vector of reduced costs cannot be generated twice. \square

In view of Theorem 4.3.1, all we need in order to guarantee finiteness of the Primal Simplex Method, is to ensure lexicographic positivity of rows $1, 2, \dots, m$ in the initial tableau. This can be achieved as follows. Recall that for the time being, we have designed the PSM only for the case when we from the very beginning have in our disposal an initial basic feasible solution. Renaming the variables, we can assume w.l.o.g. that the initial basis is $I = \{1, \dots, m\}$, so that the initial contents of the A -part of the tableau is $[A_I]^{-1}A = [I_m, [A_I]^{-1}A_I]$. Thus, i -th row in the initial tableau, $1 \leq i \leq m$, is of the form $[a, 0, \dots, 0, 1, \dots]$, where $a \geq 0$ is the value of certain basic variable in the initial primal basic feasible solution; a row of this type clearly is lexicographically positive.

A simpler pivoting rule, due to Bland, which provably prevents cycling is as follows:

Smallest subscript pivoting rule: *Given a current tableau containing positive reduced costs, find the smallest index j such that j -th reduced cost is positive; take x_j as the variable to enter the basis. Assuming that this choice of the pivoting column does not lead to immediate termination due to problem's unboundedness, choose among all legitimate (i.e., compatible with the description of the PSM) candidates to the role of the pivoting row the one with the smallest index and use it as the pivoting row.*

4.3.4 How to Start the PSM

Our description of the PSM still is incomplete; we have assumed that we know in advance a primal basic feasible solution to the problem, and to find this solution is a nontrivial (and not always achievable — what if the problem is infeasible?) task. Luckily enough, this problem can be resolved by the same PSM as applied to a properly defined auxiliary problem. We are about

to describe one of implementations of this type — the *two-phase* PSM. As applied to the LO program in the standard form

$$\max_x \{c^T x : Ax = b, x \geq 0\} \quad (4.3.2)$$

with $m \times n$ matrix A of rank m , the method works as follows.

First phase. Multiplying, if necessary, some of the equality constraints by -1 , we can enforce b to be ≥ 0 . After this, we introduce m additional variables y_1, \dots, y_m and build the auxiliary LO program

$$\text{Opt} = \max_{x,y} \left\{ -\sum_{i=1}^m y_i : Ax + y = b, x \geq 0, y \geq 0 \right\}. \quad (4.3.3)$$

Note that

- (i) the original problem is feasible iff the optimal value in the auxiliary problem is 0, and
- (ii) the auxiliary problem is feasible and bounded, and we can point out its primal basic feasible solution, specifically, $x = 0, y = b$, along with the associated basis $I = \{n+1, \dots, n+m\}$.

Using $[0; \dots; 0; b]$ as the starting point, we solve the (solvable!) auxiliary problem by the PSM, eventually arriving at its optimal solution $[x_*; y_*]$. If $y_* \neq 0$, the optimal value in the auxiliary problem is negative, meaning, by (i), that the original problem is infeasible.

In the case in question, the optimal solution λ_* to the dual to (4.3.3), which we get as a byproduct of solving (4.3.3) by the PSM, satisfies

$$d - [A, I_m]^T \lambda_* \leq 0, \lambda_*^T b = \text{Opt} < 0.$$

where $d = [0; \dots; 0; -1; \dots; -1]$ is the objective of the auxiliary problem. The vector inequality here implies that $\mu := A^T \lambda_* \geq 0$. Now, taking weighted sum of the equality constraints in the original problem, the weights being $-(\lambda_*)_i$, and adding weighted sum of the inequalities $x_j \geq 0$, the weights being μ_j , we get the inequality

$$0^T x \equiv [\mu - A^T \lambda_*]^T x \geq (-\lambda_*)^T b;$$

since $\lambda_*^T b = \text{Opt} < 0$, this inequality is contradictory, that is, not only know that the original problem is infeasible, but have in our disposal a certificate for infeasibility.

Second phase. It remains to consider the case when $y_* = 0$. In this case, x_* is a feasible solution to the original problem, and, moreover, a vertex of the feasible set X of this problem (this immediately follows from the fact that $[x_*; y_*]$ is a vertex of the feasible set X^+ of the phase I problem.). Applying the (easy-to-implement) construction we used when proving Proposition 4.2.2, we can extend the set of columns of A corresponding to the nonzero entries in x_* to a basis of the problem of interest. Now we have in our disposal both a primal basic feasible solution x_* and an associated basis for (4.3.2), and we solve this problem by the PSM.

4.3.5 Dual Simplex Method

Recall the geometric interpretation of the primal-dual pair of LO programs: we have two affine planes – the primal feasible plane \mathcal{M}_P and the dual feasible plane \mathcal{M}_D such that the corresponding linear subspaces are orthogonal complements to each other; our goal is to find in the intersections of the planes with the nonnegative orthant two orthogonal to each other vectors. When the primal problem is in the standard form (4.1.1), \mathcal{M}_P is given as $\{x : Ax = b\}$, while \mathcal{M}_D is the plane of dual slacks – vectors which can be represented as $A^T\lambda - c$. The geometry of the Primal Simplex method is as follows: at every step, we have at our disposal basis I . This basis specifies two orthogonal to each other vectors from \mathcal{M}_P and \mathcal{M}_D :

- the primal solution $x^I = (x_I = [A_I]^{-1}b, x_{\bar{I}} = 0)$. This solution satisfies the necessary condition for being a vertex of the primal feasible set: among the constraints $Ax = b, x \geq 0$ which cut this set off \mathbf{R}^n , n constraints with linearly independent vectors of coefficients, specifically, the constraints $Ax = b$ and $x_j \geq 0, j \notin I$, are satisfied as equalities;
- the dual solution $\lambda^I = [A_I]^{-T}c_I$. This solution satisfies the necessary condition for being a vertex of the dual feasible set: among the constraints $A^T\lambda - c \geq 0$ which cut this set off \mathbf{R}^m , m constraints with linearly independent vectors of coefficients, specifically, the constraints $[A^T\lambda - c]_j \geq 0$ with $j \in I$, are satisfied as equalities.

By construction, the primal solution x^I belongs to \mathcal{M}_P , the dual slack $s^I = A^T\lambda^I - c = -c^I$ belongs to \mathcal{M}_D , and x^I, s^I satisfy the complementary slackness condition – $x_j^I s_j^I = 0$ for all j .

Now, in the Primal Simplex method x^I is maintained to be primal feasible, while λ^I not necessarily is dual feasible. When λ^I happens to be dual feasible (that is, $s^I \geq 0$, or, equivalently, $c^I \leq 0$), we are done – we have built a pair of orthogonal to each other nonnegative vectors $x^I \in \mathcal{M}_P$ and $s^I \in \mathcal{M}_D$. Until it happens, we update the basis in such a way that the primal objective either remains the same (which is possible only when the current primal basic feasible solution x^I is degenerate), or is improved.

An alternative, “symmetric” course of actions would be to maintain feasibility of the dual solution λ^I , sacrificing the primal feasibility of x^I . When x^I happens to be feasible, we are done, and while it does not happen, we update the basis in such a way that the dual objective improves. This is exactly what is going on in the Dual Simplex method. One could think that this method does not deserve a separate presentation, since geometrically this is nothing as the Primal Simplex method as applied to the swapped pair of the problems – what used to be primal, now is called dual, and vice versa. This conclusion is not completely correct, since an algorithm cannot directly access geometric entities; what it needs, are algebraic descriptions of these entities, and in this respect primal-dual symmetry is not ideal – the algebraic representation of the primal feasible plane (for programs in the standard form we stick to, this is representation by system of linear equations) is not identical to the one of the dual feasible plane (which is represented in the “parametric” form $\{s = A^T\lambda - c, \lambda \in \mathbf{R}^m\}$). By the outlined reasons, it makes sense to present an explicit algorithmic description of the Dual Simplex method. This is what we do next.

A step of the Dual Simplex Method

At a step of the Dual Simplex Method (DSM) as applied to (4.1.1), we have in our disposal current basis I (i.e., an m -element subset $\{i_1, \dots, i_m\}$ of $\{1, \dots, n\}$ such that the columns A_j of A with indices from I are linearly independent) along with the corresponding basic primal solution $x^I = (x_I = [A_I]^{-1}b, x_{\bar{I}} = 0)$ which is not necessary nonnegative and the basic dual solution $\lambda^I = [A_I]^{-T}c_I$ which is dual feasible: $c^I = c - A^T\lambda^I \leq 0$. We associate with the basis

I a tableau, exactly as in the PSM:

$-c_I^T x_I^I$	$c_1^I \dots c_n^I$
$x_{i_1}^I$	$[[A_I]^{-1}A]^1$
\vdots	\dots
$x_{i_m}^I$	$[[A_I]^{-1}A]^m$

the difference with the PSM is that now all entries c_1^I, \dots, c_n^I in the zeroth row (except for the entry in the zeroth column) are nonpositive, while some of the entries $x_{i_1}^I, \dots, x_{i_m}^I$ in the zeroth column can be negative.

A. It may happen that all $x_{i_\ell}^I$, $1 \leq \ell \leq m$, are nonnegative. In this case we are done: λ^I is a feasible solution to the dual problem, x^I is a feasible solution to the primal problem, and x^I and the dual slack $-c^I$ satisfy the complementary slackness condition (since by construction of λ^I , $c_{i_\ell}^I = 0$ for all $\ell \leq m$), i.e., x^I and λ^I are optimal solutions to the respective problems.

B. Now assume that some of $x_{i_\ell}^I$ are negative. Let us pick ℓ with this property and call ℓ -th row of the tableau the *pivoting* row. We intend to eliminate i_ℓ from the basis. To this end let us look what happens when we update λ^I in such a way that i_ℓ -th reduced cost (which currently is zero) becomes $-t$, $t \geq 0$, and the reduced costs in the basis columns distinct from the i_ℓ -th column are kept zeros. In other words, we update λ^I according to $\lambda^I \mapsto \lambda(t) := \lambda^I + t[A_I]^{-T}e_\ell$. Observe that as a result of this shift, the dual objective reduces (i.e., improves); indeed,

$$b^T \lambda(t) = b^T \lambda^I + t b^T [A_I]^{-T} e_\ell = b^T \lambda^I + t e_\ell^T [[A_I]^{-1}b] = b^T \lambda^I + t x_{i_\ell}^I,$$

and $x_{i_\ell}^I < 0$. Now let us look how passing from λ^I to $\lambda(t)$ affects the vector of reduced costs. These costs $c_j(t) = [c - A^T \lambda(t)]_j$ vary as follows:

- the reduced cost in the basic column i_ℓ becomes $-t$;
- the reduced costs in all other basic columns stay zero;
- the reduced cost in a non-basic column j varies according to $c_j(t) = c_j^I - t A_j^T [A_I]^{-T} e_\ell = c_j^I - t p_j$, where p_j is the entry in the pivoting row of the tableau.

There are two possibilities:

B.1. All entries p_j , $j \geq 1$, in the pivoting row, except for those in the basic columns, are nonnegative. In this case, all reduced costs $c_j(t)$, in basic and nonbasic columns alike, are nonpositive for all $t \geq 0$, in other words, we have found an improving ray $\{\lambda(t) : t \geq 0\}$ in the dual problem; this ray certifies that the dual problem is unbounded, whence the primal problem is infeasible.

B.2. Among the entries p_j , $j \geq 1$, in the pivoting row, aside of those in the basic columns, there are negative ones. Then there exists the largest nonnegative value \bar{t} of t for which $c_j(t)$ still are nonpositive for all j , specifically, the value

$$\bar{t} = \min_{j \geq 1: p_j < 0} \frac{c_j}{p_j} = \frac{c_{j_*}}{p_{j_*}} \quad [1 \leq j_* \notin I, p_{j_*} < 0]$$

(note that we safely can write $\min_{j: p_j < 0} \frac{c_j}{p_j}$ instead of $\min_{j \notin I: p_j < 0} \frac{c_j}{p_j}$, since the entries of the pivoting row in the basic columns are nonnegative, specifically, $m - 1$ of them are zero, and remaining one is equal to 1). Observe that when we exclude from the basis I the basic column A_{i_ℓ} and add to the basis the index $j_* \notin I$, we get a basis, and this is the new basis I^+ we deal with, with $\lambda^{I^+} = \lambda(\bar{t})$ being a new dual basic feasible solution.

Indeed, assuming that I^+ is not a basis, the column A_{j_*} is a linear combination of the $m - 1$ columns A_{i_ν} , $1 \leq \nu \leq m$, $\nu \neq \ell$: $A_{j_*} = \sum_{\substack{\nu: 1 \leq \nu \leq m \\ \nu \neq \ell}} y_\nu A_{i_\nu}$. But then

$$p_{j_*} = A_{j_*}^T [A_I]^{-T} e_\ell = \sum_{\substack{\nu: 1 \leq \nu \leq m \\ \nu \neq \ell}} y_\nu [[A_I]^{-1} A_{i_\nu}]^T e_\ell = \sum_{\substack{\nu: 1 \leq \nu \leq m \\ \nu \neq \ell}} y_\nu e_\nu^T e_\ell = 0,$$

which is impossible, since p_{j_*} is negative.

We then update the information in the tableau, exactly as in the PSM, specifically,

- call the column j_* the *pivoting column*, and the entry p_{j_*} in the intersection of the pivoting row and the pivoting column – the *pivoting entry*;
- replace the pivoting row with its normalization obtained by dividing all entries in the row, including the one in the zero column, by the pivoting entry, and replacing the label x_{i_ℓ} of this row with x_{j_*} ;
- update all other rows of the tableau, including the zeroth, by subtracting from them multiples of the normalized pivoting row, where the multiples are chosen in such a way that the entry of the updated row in the pivoting column j_* becomes zero, and proceed to the next iteration of the DSP.

Dual Simplex Method: convergence

Observe that as a result of the iteration, we either

(a) conclude correctly that the current dual basic feasible solution is optimal and augment it by an optimal primal basic solution, or

(b) conclude correctly that the dual problem is unbounded (and therefore the primal problem is unsolvable), or

(c) pass from the current dual basic feasible solution to another solution of the same type, but with strictly smaller value of the dual objective, or keep the dual solution intact and update the basis only. The second option is possible only when λ^I is a *degenerate* solution, meaning that not all nonbasic reduced costs corresponding to λ^I are strictly negative.

In view of these observations, exactly the same argument as in the PSM case leads to the following conclusion:

Corollary 4.3.2 *The Dual Simplex method, initiated at a dual basic feasible solution of (4.2.1), possesses the following property: if the method terminates at all, the result upon termination either is a pair of primal and dual basic feasible solutions which are optimal for the primal program (4.1.1), (4.2.1), or is a correct claim that the primal problem is infeasible. In the second case, the method produces a ray which is contained in the feasible set of the dual problem and is a ray along which the dual objective decreases, so that this ray is a certificate of primal infeasibility. In fact, this ray is an extreme ray of the recessive cone of the dual feasible set.*

The method definitely terminates in finitely many steps, provided that the program is dual nondegenerate (i.e., all dual basic feasible solutions are so).

Similarly to the PSM, the Dual Simplex Methods admits pivoting rules which prevent cycling, various techniques for building the initial basic dual feasible solution, etc., see [3].

4.3.6 “Warm Start”

Assume we have solved LO program (4.1.1) to optimality by either Primal, or Dual Simplex method, and thus have in our disposal a basis I which gives rise to feasible primal and dual solutions satisfying the complementary slackness condition and thus optimal for the respective programs. We are about to understand how this basis helps to solve a “close” LO program. This necessity arises when we intend to solve series of relatively close to each other LO programs, as it is the case, e.g., in branch and bound type methods of Integer Programming.

Recall that the optimal basis is characterized by two requirements:

$$\begin{array}{ll} [A_I]^{-1}b \geq 0 & \text{[feasibility]} \\ c - A^T[A_I]^{-T}c_I \leq 0 & \text{[optimality]} \end{array}$$

When these requirements are satisfied, $x^I = (x_I = [A_I]^{-1}b, x_{\bar{I}} = 0)$ is an optimal primal basic solution, and $\lambda_I = [A_I]^{-T}c_I$ is an optimal dual basic solution.

We now consider several typical updatings of the problem.

New variable is added

Assume we extend x with a new decision variable x_{n+1} , A – with a new column A_{n+1} , and c – with a new entry c_{n+1} , keeping the rest of the data and the standard form of the problem intact. I still is a basis for the new problem, and we do not affect the feasibility condition. As far as optimality condition is concerned, it remains satisfied when

$$c_{n+1} - A_{n+1}^T[A_I]^{-T}c_I \leq 0. \quad (!)$$

If this easy to verify condition holds true, x^I is an optimal solution to the new primal problem, and λ^I is an optimal solution to the new dual problem. If (!) is not satisfied, we can think of I as of the current basis for the PSM as applied to the new problem, and of x_{n+1} as of the variable entering this basis, and run PSM until the new problem is solved. This is called “warm start,” and usually with such a warm start the solution of the new problem takes significantly less time than if we were solving it from scratch.

Changes in the cost vector c

When we replace the cost vector c with $\bar{c} = c + t\delta c$, where δc is the “direction of change,” and $t \in \mathbf{R}$ is the “step along this direction,” the feasibility conditions remain intact; in order for optimality conditions to be satisfied, the perturbation should satisfy the requirement

$$\bar{c}^I = \bar{c} - A^T[A_I]^{-T}\bar{c}_I = c^I + t[\delta c - A^T[A_I]^{-T}\delta c_I] \leq 0.$$

Note that given δc and t , this fact is easy to verify; moreover, we can easily find the largest range T of values of t such that \bar{c}^I has nonpositive nonbasic components. If the actual perturbation is “too large” to satisfy this requirement and some entries in the new vector of reduced costs are positive, we can run the PSM on the new problem starting with the basis I until the new problem is solved. This warm start usually saves a lot of computational effort as compared to solving the new problem from scratch.

Note that even when the shift $c \mapsto c + t\delta c$ keeps x^I primal optimal, the optimal dual solution can change — it becomes $[A_I]^{-T}[c_I + t\delta c_I]$, and thus changes, unless $t = 0$ or $\delta c_I = 0$.

Changes in the right hand side vector b

Now assume that we perturb the right hand side vector b according to $b \mapsto b + t\delta b$. I still is a basis, and the optimality condition remains intact. In order for the feasibility condition to remain valid, we need

$$[A_I]^{-1}[b + t\delta b] \geq 0,$$

and here again we can easily find the largest range of values of t where the latter condition holds true. When t is in this range, we easily get a new primal optimal solution, while the optimal dual solution remains intact. If t is outside of the indicated range, we still have in our disposal a dual basic feasible solution for the new problem, and we can start at this solution the DSM to solve the new problem to optimality.

Change in a nonbasic column of A

When $j \notin I$, and we perturb j -th column of A according to $A_j \mapsto A_j + t\delta a$, x^I remains a basic feasible solution to the new problem, A_I remains intact, and the only important for us entity which can change is the j -th entry in the vector of reduced costs which changes according to

$$(c^I)_j \mapsto (c^I)_j - t(\delta a)^T [A_I]^{-T} c_I.$$

As above, we can easily find the largest range of values of t in which the perturbed reduced cost remains nonpositive, meaning that in this range both primal and dual optimal solutions remain intact. If perturbation in A_j runs out of this range, we can solve the new problem with the PSM started at the basis I , with the variable x_j entering the basis.

New equality constraint is added to the primal problem

Assume that A is augmented by a new row, a_{m+1}^T , and b – by the corresponding new entry b_{m+1} , so that the constraint matrix in the new problem is $A_+ = [A; a_{m+1}^T]$, and the right hand side vector in the new problem is $b_+ = [b; b_{m+1}]$. In order to process the new problem, we check whether the rows in A_+ are linearly independent; if this is not the case, the new system of equality constraints is either infeasible, or the added equality constraint is redundant and does not affect the problem. When the rows of A_+ are linearly independent, we proceed as follows. We can easily find $\delta\lambda_i$, $1 \leq i \leq m$, such that $a_{m+1,j} = \sum_{i=1}^m \delta\lambda_i a_{ij}$ for all $j \in I$; indeed, $\delta\lambda = [A_I]^{-T} [a_{m+1}]_I$. Now let $\bar{\lambda}$ be the optimal dual basic solution we end up with when solving the old problem, and let $\lambda(t) = [\bar{\lambda} + t\delta\lambda; -t]$. Then $[A_+]^T \lambda(t) = A^T \bar{\lambda} + tp$, $p = A^T \delta\lambda - a_{m+1}$. Observe that the entries of p with indices from I are zero, while p itself is nonzero, since the rows of A_+ are linearly independent. It follows that the reduced costs $c_j(t) = [c - A_+^T \lambda(t)]_j$ corresponding to the solution $\lambda(t)$ of the new dual problem remain zero when $j \in I$, while some of the $c_j(t)$ with $j \notin I$ are nonconstant linear functions of t . Let J be the set of those j for which $c_j(t)$ are nonconstant functions of t . When $t = 0$, all $c_j(t)$ are nonpositive; it follows that we can easily find a value $\bar{t} \in \mathbf{R}$ of t such that all $c_j(\bar{t})$ are nonpositive, and at least one of $c_j(\bar{t})$ with $j \in J$ is zero, let this value of j be denoted by j_* . Setting $I_+ = I \cup \{j_*\}$, it is immediately seen that the columns $[A_+]_j$, $j \in I_+$, of A_+ are linearly independent, so that I_+ is a basis of the new problem.

Indeed, since the columns a_j , $j \in I$, of A are linearly independent, so are the columns $[A_+]_j$, $j \in I$. It follows that the only possibility for the columns $[A_+]_j$, $j \in I_+$, to be linearly dependent is that $[A_+]_{j_*} = \sum_{j \in I} y_j [A_+]_j$ for some y_i . But

then $\lambda^T(t)[A_+]_{j_*} = \sum_{j \in I} y_j \lambda^T(t)[A_+]_j = \sum_{j \in I} y_j [A_j^T \bar{\lambda} + t p_j] = \sum_{j \in I} y_j [A_j^T \bar{\lambda}]$, since $p_j = 0$ for $j \in I$. We see that $\lambda^T(t)[A_+]_{j_*}$, and thus $c_{j_*}(t)$, is independent of t , which is not the case.

By construction, setting $\tilde{\lambda} = \lambda(\bar{t})$, we have that $c - A_+^T \tilde{\lambda} \leq 0$ and $(c - A_+^T \tilde{\lambda})_{I_+} = 0$, i.e., we have in our disposal a dual basic feasible solution associated with the basis I_+ of the new problem. We now can use I_+ and $\tilde{\lambda}$ to run the DSM on the new problem.

Lecture 5

The Network Simplex Algorithm

In this lecture, we present a version of the Simplex method for solving the *Network Flow* problem – the single-commodity version of the multicommodity network flow problem (p. 12 in section 1.1.3). The presence of additional structure – the graph underlying the problem – allows for significant modifications and simplifications in the prototype Simplex algorithm and thus deserves a dedicated description.

Our presentation follows [3, Chapter 7], where an interested reader can find a much broader picture of network flow algorithms.

5.1 Preliminaries on Graphs

5.1.1 Undirected graphs

An *undirected graph* $G = (\mathcal{N}, \mathcal{E})$ is a pair of two finite sets. The first, \mathcal{N} , is called the set of *nodes* and can be an arbitrary *nonempty* finite set; without loss of generality, we can identify the nodes with the integers $1, \dots, m$, where $m = \text{Card } \mathcal{N}$ is the number of elements in \mathcal{N} . The elements of the second set \mathcal{E} , called *arcs*, are distinct from each other *two-element subsets* of the set of nodes; thus, an arc is an *unordered pair* $\{i, j\}$ of two *distinct* nodes i, j . Note that \mathcal{E} , in contrast to \mathcal{N} , is allowed to be empty. We say that the nodes i, j are *incident* to the arc $\{i, j\}$, and the arc *links* the nodes i, j .

Walks, paths, cycles. A *walk* in an undirected graph G is an ordered collection i_1, \dots, i_k of nodes such that every two consecutive nodes in this collection are linked by an arc in G , that

Figure 5.1: Graphs: left – undirected graph; right – directed graph

is, $\{i_s, i_{s+1}\} \in \mathcal{E}$, $1 \leq s \leq k-1$. A walk i_1, \dots, i_t is called a *path*, if all the nodes i_1, \dots, i_t are distinct from each other. A walk i_1, \dots, i_t is called a *cycle*, if the nodes i_1, \dots, i_{t-1} are distinct from each other, $i_t = i_1$ and, in addition, $t \geq 3$. For example, in the undirected graph depicted on figure 5.1 (left):

- $\mathcal{N} = \{1, 2, 3, 4\}$, $\mathcal{E} = \{\{1, 2\}, \{2, 3\}, \{1, 3\}, \{3, 4\}\}$;
- 1, 3, 2, 3, 4 is a walk, but not a path;
- 1, 2, 3, 4 is a path;
- 1, 2, 3, 1 is a cycle, while 1, 2, 3 and 1, 2, 1 are not cycles.

Connectedness. An undirected graph is called *connected*, if there exists a walk passing through all nodes. For example, the graph on figure 5.1 (left) is connected.

Leaves. A node in an undirected graph is called *isolated*, if it is not incident to any arc (for a connected graph, such a node exists only in the trivial case of a single-node graph). A node is called a *leaf*, if it is incident to exactly one arc. For example, node 4 of the graph on figure 5.1 (left) is a leaf, and all other nodes are not leaves.

Trees. An undirected graph $G = (\mathcal{N}, \mathcal{E})$ is called a *tree*, if it is connected and does not have cycles. The graph on figure 5.1 (left) is not a tree; we can make it a tree by removing any one of the arcs $\{1, 2\}$, $\{1, 3\}$, $\{2, 3\}$. Trees play important role in the simplex-type network flow algorithms, and we are about to summarize here the properties of trees needed in the sequel.

Theorem 5.1.1 (i) *Every tree with more than one node has a leaf.*

(ii) *An undirected graph $(\mathcal{N}, \mathcal{E})$ is a tree with m nodes if and only if it is connected and has exactly $m - 1$ arcs;*

(iii) *For every two distinct nodes i, j in a tree, there exists exactly one path which starts at i and ends at j ;*

(iv) *When extending the set of arcs of a tree by adding a new arc, the resulting graph gets exactly one cycle¹*

Proof. (i): Assume that we are given a tree with more than one node and without leaves, and let us lead this assumption to a contradiction. Since our tree is connected and does not have leaves, every node is incident to at least two arcs. Now let us walk along the tree as follows: we start from an arbitrary node; after arriving at a node along certain arc, we leave it along another arc incident to this node (since every node is incident to at least two arcs, an “exiting arc” always can be found). Since the number of nodes is finite, eventually we will visit for the second time a node i which we have already visited; when it happens for the first time, the segment of our walk from leaving i on the first visit to the node to entering i on the second visit to it is a cycle (recall that we exit a node by an arc distinct from the one used to enter the node, so that the above segment cannot be of the form i, j, i and thus indeed is a cycle). Since a tree does not have cycles, we get a desired contradiction.

(ii): Let us prove by induction in m that every tree with m nodes has $m - 1$ arcs. When $m = 1$,

¹It is assumed here that when counting cycles, we do not distinguish between the cycles like a, b, c, d, a and b, c, d, a, b (the same “loop” along which we move starting from different nodes), same as do not distinguish between the cycles like a, b, c, d, a and a, d, c, b, a (the same “loop” along which we move in two opposite directions).

the statement clearly is true. Assuming that the statement is true for m -node trees, let us prove that it is true for every tree with $m+1$ nodes. Thus, let $G = (\mathcal{N}, \mathcal{E})$ be a tree with $m+1$ nodes; we should prove that G has exactly m arcs. By (i), G has a leaf i ; removing from the nodal set this node, and from the set of arcs – the (unique) arc incident to the leaf i , we get an m -nodal graph G' which clearly is connected along with G ; since every cycle in G' clearly is a cycle in G , G' , along with G , has no cycles. Thus, G' is a tree, and by inductive hypothesis, G' has $m-1$ arcs, whence G has m arcs, as claimed. The induction is complete.

It remains to prove that every connected m -nodal graph $G = (\mathcal{N}, \mathcal{E})$ with $m-1$ arcs is a tree. If G has a cycle and we eliminate from \mathcal{E} an arc from this cycle, we clearly keep the resulting graph connected; if it still has cycles, we can remove in a similar fashion another arc, keeping the graph connected, and so on. As a result, we will end up with a *connected* m -node graph which has no cycles and thus is a tree; by the statement we have already proved, the resulting graph has $m-1$ arcs – as much as G itself. This is possible only when no arcs were actually removed, that is, G itself does not have cycles and thus is a tree.

(iii): Let G be a tree, and i, j be two distinct nodes of G . Since G is connected, there exists a walk which starts at i and ends at j . The smallest, in the number of nodes incident to it, walk of this type clearly is a path. Now, if there are two distinct from each other paths of this type, then we can build a walk from i to i which first goes from i to j along the first path and then goes back from j to i along the “inverted” second path. Unless the paths are identical, the resulting “loop” clearly contains one or more cycles, which is impossible, since G is a tree.

(iv): Let G be a tree with m nodes (and thus, by (ii), $m-1$ arcs). When extending the set \mathcal{E} of arcs of G with an arc $\{i, j\}$ which is not in the set, we get a connected graph G' which is not a tree (indeed, this graph has m nodes and m arcs, which is forbidden for a tree by (ii)). Since G' is connected and is not a tree, it has a cycle; this cycle clearly contains the arc $\{i, j\}$ (otherwise it would be a cycle in G , and G does not have cycles). Since all arcs $\{i_s, i_{s+1}\}$, in a cycle $i_1, \dots, i_{t-1}, i_t = i_1$ are distinct from each other, the part of the cycle obtained when eliminating the arc $\{i, j\}$ is a path in G which links j and i . By (iii), such a path is unique, whence the cycle in question also is unique, since, by our analysis, it must be obtained by “closing” the added arc $\{i, j\}$ by the unique path from j to i in G . \square

Subgraphs of a graph. Let $G = (\mathcal{N}, \mathcal{E})$ be an undirected graph. An undirected graph $G' = (\mathcal{N}', \mathcal{E}')$ is called a *subgraph* of G , if $\mathcal{N}' \subset \mathcal{N}$ and $\mathcal{E}' \subset \mathcal{E}$. In other words, a subgraph is what we can get from G by eliminating from \mathcal{N} part of the nodes to get \mathcal{N}' and eliminating from \mathcal{E} part of the arcs, *including all arcs which do not link pairs of nodes from \mathcal{N}'* , to get \mathcal{E}' . For example, the graph with the nodes 1,3,4 and the arcs $\{1, 3\}, \{1, 4\}$ is a subgraph of the graph presented on figure 5.1 (left).

Spanning trees. A subgraph of an undirected graph $G = (\mathcal{N}, \mathcal{E})$ is called a *spanning tree*, if it is a tree with the same set of nodes as G ; in other words, a spanning tree is a tree of the form $T = (\mathcal{N}, \mathcal{E}')$, where $\mathcal{E}' \subset \mathcal{E}$.

Theorem 5.1.2 *Let $G = (\mathcal{N}, \mathcal{E})$ be a connected undirected graph and \mathcal{E}_0 be a subset of arcs of G such that there is no cycle in G with all arcs belonging to \mathcal{E}_0 . Then there exists a spanning tree $T = (\mathcal{N}, \mathcal{E}_1)$ of G such that $\mathcal{E}_0 \subset \mathcal{E}_1$.*

Proof. Let $G = (\mathcal{N}, \mathcal{E})$ and \mathcal{E}_0 be as in the premise of the theorem. If G is a tree, we can set $\mathcal{E}_1 = \mathcal{E}$, and we are done. Otherwise G contains a cycle. The arcs in this cycle cannot all belong

to \mathcal{E}_0 , and thus the cycle contains an arc which does not belong to \mathcal{E}_0 . Let us remove this arc from \mathcal{E} . The resulting graph G' can be a tree, and we can take as \mathcal{E}_1 the set of its arcs; otherwise we can repeat the above transformation with G' in the role of G . This process clearly cannot last forever, and when it stops, we have in our disposal a spanning tree $(\mathcal{N}, \mathcal{E}_1)$ with $\mathcal{E}_0 \subset \mathcal{E}_1$, as claimed. \square

Corollary 5.1.1 *Let $G = (\mathcal{N}, \mathcal{E})$ be an undirected graph with m nodes, $m - 1$ arcs and no cycles. Then G is a tree.*

Proof. All we should prove is that G is connected. Assume that this is not the case. Then G can be split into $k \geq 2$ connected components – *connected* subgraphs G_1, \dots, G_k – in such a way that

- the nodal sets $\mathcal{N}_1, \dots, \mathcal{N}_k$ of the subgraphs form a partition of the nodal set \mathcal{N} of G into non-overlapping components,
- the set \mathcal{E}_ℓ of arcs of G_ℓ is comprised of *all* arcs of G linking the nodes from \mathcal{N}_ℓ , $1 \leq \ell \leq k$;
- we have $\mathcal{E} = \mathcal{E}_1 \cup \dots \cup \mathcal{E}_k$, that is, there are no arcs in G which start in one of the sets \mathcal{N}_ℓ and end in another of these sets.

To get this partition, let us take a node and define \mathcal{N}_1 as the set of all nodes which can be reached from this node by a walk. Defining \mathcal{E}_1 as the set of all arcs of G which link the nodes from \mathcal{N}_1 , note that by construction of \mathcal{N}_1 , no other arc is incident to a node from \mathcal{N}_1 . If the resulting graph $(\mathcal{N}_1, \mathcal{E}_1)$ differs from G , the remaining nodes and arcs of G form a graph, and we can repeat the same construction for this graph, and so on.

Let the cardinalities of \mathcal{N}_ℓ be m_ℓ . Since G does not have cycles, so are the components of G , and since they are connected, they are trees. By Theorem 5.1.1, ℓ -th component has $m_\ell - 1$ arcs, and thus the total number of arcs in G is $\sum_{\ell=1}^k m_\ell - k = m - k$. Since $k > 1$ and G has $m - 1$ arcs, we get a contradiction. \square

5.1.2 Directed graphs

A *directed graph* is a pair of two finite sets, the (nonempty) *set of nodes* \mathcal{N} and (possibly empty) *set of arcs* \mathcal{E} , where an arc is an *ordered pair* (i, j) of two *distinct* from each other nodes $i, j \in \mathcal{N}$. We say that an arc $(i, j) \in \mathcal{E}$ *starts* at node i , *ends* at node j and *links* nodes i and j . For example, the oriented graph depicted on figure 5.1 (right) has the nodal set $\mathcal{N} = \{1, 2, 3, 4\}$, and the set of arcs $\mathcal{E} = \{(1, 2); (1, 3), (2, 3), (3, 4)\}$. For a oriented graph, it is legitimate to include “inverse to each other” pairs of arcs (i, j) and (j, i) – an option impossible for an undirected graph. However, in both directed and undirected cases we forbid arcs with identical to each other endpoints.

A *walk* in an oriented graph is a sequence i_1, \dots, i_t of nodes *augmented with a sequence* $\gamma_1, \dots, \gamma_{t-1}$ of arcs such that for every $s < t$ either $\gamma_s = (i_s, i_{s+1})$, or $\gamma_s = (i_{s+1}, i_s)$. Informally speaking, when walking along a directed graph, we are allowed to move through arcs, but not necessary in the directions of these arcs. The arcs γ_s along which we move in their direction (that

is, $\gamma_s = (i_s, i_s + 1) \in \mathcal{E}$) are called *forward arcs* of the walk, and the arcs γ_s along which we move in the direction opposite to the one of the arc, (i.e., $\gamma_s = (i_{s+1}, i_s) \in \mathcal{E}$) are called *backward arcs*. A walk $i_1, \gamma_1, i_2, \gamma_2, \dots, i_{t-1}, \gamma_{t-1}, i_t$ is called a *path*, if the nodes i_1, \dots, i_t are distinct from each other. For example, the sequence $i_1 = 1, \gamma_1 = (1, 2), i_2 = 2, \gamma_2 = (2, 3), i_3 = 3, \gamma_3 = (1, 3), i_4 = 1$ is a walk in the oriented graph depicted on figure 5.1 (right), the forward arcs being γ_1, γ_2 and the backward arc being γ_3 . This walk is not a path; to get a path, we could, e.g., eliminate from the walk the arc γ_3 and the last node $i_4 = 1$.

Given an directed graph, we can convert it into an undirected one, keeping the set of nodes intact and passing from oriented arcs (i.e., ordered pairs of nodes) to their unordered counterparts; needless to say, opposite to each other arcs $(i, j), (j, i)$ in the oriented graph, if any are present, lead to the same arc $\{i, j\} = \{j, i\}$ in the undirected graph. Note that the undirected graph on figure 5.1 (left) is obtained in the outlined way from the directed graph depicted on the right half of the same figure.

A directed graph is called *connected*, if there is a walk passing through all the nodes, or, which is the same, if the undirected counterpart of the graph is connected.

5.2 The Network Flow Problem

Recall the single-commodity version of the Multicommodity Network Flow problem (p. 12 in section 1.1.3):

Given

- a directed graph $G = (\mathcal{N} = \{1, \dots, m\}, \mathcal{E})$,
- a vector s of external supplies at the nodes of G ,
- a vector u of arc capacities, and
- a vector c of transportation costs of the arcs,

find a feasible flow f with the smallest possible transportation cost.

Recall that

- a supply s is a vector with entries indexed by the nodes of G ;
- a flow f is any vector f_{ij} with entries indexed by the arcs (i, j) of G ;
- a flow is *feasible* if it
 - is nonnegative and respects the capacities of the arcs:

$$0 \leq f_{ij} \leq u_{ij} \quad \forall (i, j) \in \mathcal{E}$$

- respects the *flow conservation law*

$$\forall i \leq n : s_i + \sum_{j: (j, i) \in \mathcal{E}} f_{ji} = \sum_{j: (i, j) \in \mathcal{E}} f_{ij}$$

or, in words, for every node, the sum of the external supply at the node plus the total incoming flow of the node is equal to the total outgoing flow of the node.

Recall that the *incidence matrix* of a directed graph $G = (\mathcal{N}, \mathcal{E})$ with $n = \text{Card}\mathcal{E}$ arcs and $m = \text{Card}\mathcal{N}$ nodes is the $m \times n$ matrix $P = [P_{i\gamma}]$ with the rows indexed by the nodes $i = 1, \dots, m$ of the graph, and the columns indexed by the arcs $\gamma \in \mathcal{E}$, defined by the relation

$$P_{ij} = \begin{cases} 1, & \text{node } i \text{ starts arc } \gamma \\ -1, & \text{node } i \text{ ends arc } \gamma \\ 0, & \text{in all other cases} \end{cases},$$

and in terms of this matrix, the flow conservation law reads

$$Pf = s.$$

Thus, the Network Flow problem reads

$$\min_f \left\{ c^T f := \sum_{\gamma \in \mathcal{E}} c_\gamma f_\gamma : \begin{array}{l} Pf = s \\ 0 \leq f \leq u \end{array} \right\} \quad (5.2.1)$$

5.3 The Network Simplex Algorithm

Here we present a variant of the Primal Simplex method aimed at solving the *uncapacitated* version of the network flow problem (5.3.1), that is, the problem

$$\min_f \left\{ c^T f := \sum_{\gamma \in \mathcal{E}} c_\gamma f_\gamma : Pf = s, f \geq 0 \right\} \quad (5.3.1)$$

obtained from (5.3.1) by letting all arc capacities to be $+\infty$.

5.3.1 Preliminaries

From now on, we make the following

Assumption A: *The graph G is connected, and $\sum_{i \in \mathcal{N}} s_i = 0$.*

Note that when G is not connected, it can be split into connected components. It is clear that the network flow problems (5.3.1), (5.2.1) reduce to series of uncoupled similar problems for every one of the components, so that the assumption that G is connected in fact does not reduce generality. Further, the sum of rows of an incidence matrix clearly is 0, meaning that Pf is a vector with zero sum of entries for every flow f . In other words, the assumption $\sum_{i \in \mathcal{N}} s_i = 0$ is *necessary* for a network flow problem, capacitated or uncapacitated alike, to be feasible. The bottom line is that Assumption A in fact does not restrict generality.

5.3.2 Bases and Basic Feasible Solutions

We intend to solve problem (5.2.1) by the Primal Simplex Method somehow adjusted to the specific structure of the problem. Note that this problem is in the standard form, as is needed by the method. It remains to take care of the rank of the constraint matrix (the method “wants” it to be equal to the number of rows in the matrix) and to understand what are its bases. Our immediate observation is that the constraint matrix P arising in (5.2.1) has linearly dependent rows – their sum is the zero vector, in contrast to what we need to run the Simplex method.

The remedy is simple: linear dependence of the vectors of coefficients in equality constraints of an LO problem, depending on the right hand side, either makes the problem infeasible, or allows to eliminate the equality constraints which are linear combinations of the remaining equality constraints. Under Assumption A, every one of equality constraints in (5.2.1) is just the minus sum of the remaining equality constraints (recall that $\sum_i s_i = 0$), and therefore when eliminating it, we get an equivalent problem. For the sake of definiteness, let us eliminate the last, m -th equality constraint, thus passing to the equivalent problem

$$\min_f \{c^T f : Af = b, f \geq 0\}, \quad (5.3.2)$$

where A is the $(m-1) \times n$ matrix comprised of the first $m-1$ rows of P , and $b = [s_1; \dots; s_{m-1}]$. We shall see in a while that the resulting constraint matrix A has linearly independent rows, as required by the Simplex method. This result will be obtained from a very instructive description of basic feasible solutions we are about to derive.

Basic solutions are tree solutions

Recall that the Primal Simplex method works with *bases* – sets I of (indexes of) the columns of A such that the corresponding submatrix of A is square and nonsingular – and with the corresponding basic solutions f^I uniquely defined by the requirements that $Af^I = b$ and the entries of f^I with indexes outside of I are zeros. In the case of problem (5.3.2), the bases should be sets of $m-1$ arcs of G (since these are the arcs which index the columns in A) such that the corresponding $m-1$ columns of A are linearly independent. We are about to describe these bases and to present a simple specialized algorithm for finding the associated basic solutions.

Let $I \in \mathcal{E}$ be a set of $m-1$ arcs of G such that the undirected counterpart G_I associated with the subgraph $G_I = (\{1, \dots, m\}, I)$ is a tree; in the sequel, we shall express this fact by the words “the arcs from I form a tree when their directions are ignored.” Note that by Theorem 5.1.1, this tree has $m-1$ arcs, meaning that the set I (which contains $m-1$ oriented arcs) does not contain pairs of inverse to each other arcs (i, j) , (j, i) , and thus different arcs in I induce different non-oriented arcs in G_I .

Lemma 5.3.1 *Let I be the set of $m-1$ arcs in G which form a tree when their directions are ignored. Whenever a vector of external supplies s satisfies $\sum_i s_i = 0$, there exists an associated flow f (that is, a flow satisfying $Pf = s$) such that $f_\gamma = 0$ when $\gamma \notin I$, and such a flow is unique.*

Proof. Let B be the $(m-1) \times (m-1)$ submatrix of A comprised of columns which are indexed by arcs from I . We should prove that whenever $b \in \mathbf{R}^{m-1}$, the system of equations $Bx = b$ has exactly one solution, or, equivalently, that B is nonsingular. Let us call the last node of G the *root node*; this is the only node which does not correspond to a row in A . By Theorem 5.1.1, for every other node there exists a unique path in G_I which links the node with the root node. We clearly can renumber the nodes of G in such a way that the new indexes i' of the nodes i would increase along every such path². We then associate with every arc $\gamma = (i, j) \in I$ the serial number $\min[i', j']$. Clearly, different arcs in I get different numbers (otherwise G_I would

²this is how it can be done: let $d(i)$ be the “distance” from a node i to the root node in G_I , that is, the number of arcs in the unique path of G_I which links i and the root node. We give to the root node index m (as it used to be). We then order all the nodes according to their distances to the root, ensuring that these distances form a non-ascending sequence. The new index i' of a node i is the serial number of this node in the above sequence.

have cycles). The incidence matrix P' of the graph with renumbered nodes is obtained from P by permuting rows, and this permutation does not move the last row (since by construction $m' = m$), so that the matrix A' which we get when eliminating from P' the last row is obtained from A by permuting rows. Consequently, the submatrix of A' comprised of columns indexed by $\gamma \in I$ is obtained from B by permuting rows. Numbering the columns in this submatrix of A' according to the serial numbers we gave to the arcs from I , we get a $(m-1) \times (m-1)$ matrix B' which is obtained from B by permuting rows and then permuting columns; clearly, B is nonsingular if and only if B' is so. Now, ℓ -th column of B' corresponds to an arc (i, j) from I such that $\min(i', j') = \ell$; the nonzero entries in the corresponding column of P have row indexes i and j , and in P' – row indexes i' and j' ; since $\ell = \min[i', j']$, one of these row indexes is ℓ , and the other one is $> \ell$, meaning that B' is low-triangular with nonzero diagonal entries. Thus, B' , and then B , is nonsingular. \square

Corollary 5.3.1 *The rank of the matrix A in (5.3.2) is $m-1$, that is, the rows of A are linearly independent.*

Proof. Since G is connected, there is a set I of $m-1$ arcs of G which from a tree after their directions are ignored (apply Theorem 5.1.2 to an empty set \mathcal{E}_0 of arcs). By Lemma 5.3.1, the columns of A indexed by the $m-1$ arcs of I are linearly independent. Thus, the $(m-1) \times n$ matrix A has a $(m-1) \times (m-1)$ nonsingular submatrix. \square

Now we are ready to describe the bases of A . Observe that by definition of a base, this is an $(m-1)$ -element subset of indices of the columns in A (i.e., and $(m-1)$ -element set of arcs in G) such that the corresponding columns of A are linearly independent.

Theorem 5.3.1 *An $(m-1)$ -element set I of arcs in G is a base of A if and only if the arcs from I form a tree when their directions are ignored.*

Proof. In one direction – if $m-1$ arcs of G form a tree after their directions are ignored, then the set I of these arcs is a base of A – the fact was already proved. To prove it in opposite direction, let I be a set of $m-1$ arcs which is a basis; we should prove that after the directions of these arcs are ignored, they form a tree. First, we claim that I does not contain any pair of “inverse to each other” arcs (i, j) , (j, i) . Indeed, for such a pair, the sum of the corresponding columns of P (and thus of A) is zero, while the columns of A indexed by arcs from I are linearly independent. Since I does not contain pairs of inverse to each other arcs, different arcs from I induce different arcs in G_I , meaning that the undirected m -node graph G_I has $m-1$ arcs. We want to prove that the latter graph is a tree; invoking Corollary 5.1.1, all we need to prove is that G_I has no cycles. Assuming that this is not the case, let $i_1, i_2, \dots, i_{t-1}, i_t = i_1$, $t \geq 4$, be a cycle in G_I , meaning that I contains arcs $\gamma_1, \dots, \gamma_{t-1}$ where γ_ℓ is either $(i_\ell, i_{\ell+1})$, or $(i_{\ell+1}, i_\ell)$. Observe that all $t-1$ arcs γ_ℓ are distinct from each other. Now let ϵ_ℓ be equal to 1 when $\gamma_\ell = (i_\ell, i_{\ell+1})$ and $\epsilon_\ell = -1$ otherwise. It is immediately seen that the flow f with $f_\gamma = \epsilon_\ell$ for $\gamma = \gamma_\ell$ and $f_\gamma = 0$ when γ is distinct from $\gamma_1, \dots, \gamma_{t-1}$ satisfies $Pf = 0$, meaning that the columns of P indexed by $\gamma_1, \dots, \gamma_{t-1}$ are linearly dependent. Since $\gamma_\ell \in I$, the columns of P indexed by $\gamma \in I$ also are linearly independent, which is a desired contradiction. \square

Integrality of basic feasible solutions. As a byproduct of the above considerations, we get the following important result:

Proposition 5.3.1 *Let the right hand side vector b in (5.3.2) be integral. Then every basic solution to the problem, feasible or not, is an integral vector.*

Proof. By Theorem 5.3.1, the bases of A are exactly the $(m-1)$ -element sets of arcs in Γ which form trees when the directions of the arcs are ignored. From the proof of Lemma 5.3.1 it follows that the associated $(m-1) \times (m-1)$ submatrices B of A after reordering of rows and columns become lower triangular with nonzero diagonal entries. Since every entry in A is either 1, or -1 , or 0, every lower triangular matrix B' in question has integral entries and diagonal entries ± 1 , whence the entries in the inverse of B' are integral as well. Therefore, if B is a basic submatrix of A and b is an integral vector, the vector $B^{-1}b$ is integral, meaning that the nonzero entries in every basic solution to $Ax = b$ are integral. \square

Algorithm for building basic solutions. Theorem 5.3.1 says what are the basic solutions to the uncapacitated network flow problem (5.3.2) – these are exactly the *tree solutions*, those which can be obtained as follows:

- we choose in the set \mathcal{E} of arcs of G a subset I of $m-1$ arcs which form a tree when their directions are ignored;
- the tree solution associated with I is a flow f such that $f_\gamma = 0$ for $\gamma \notin I$ and $Af = b := [s_1; \dots; s_{n-1}]$. These conditions uniquely define f (Lemma 5.3.1), and in fact f is given by the following simple algorithm. Let G_I be the m -node tree associated with I . To get f , we process this tree in $m-1$ steps as follows:
 - At the beginning of step $t = 1, 2, \dots, m-1$ we have in our disposal a $m-t+1$ -node subgraph $G^t = (\mathcal{N}^t, \mathcal{E}^t)$ of G_I which is a tree, and a vector s^t of external demands at the nodes of G^t satisfying the relation $\sum_{i \in \mathcal{N}^t} s_i^t = 0$. At the first step, G^1 is G_I , and $s^1 = s$.
 - At step t , we act as follows:
 1. We identify a leaf of G^t , let it be denoted by \bar{i} ; such a leaf exists by Theorem 5.1.1. By the definition of a leaf, in G^t there exists a unique arc $\{j, \bar{i}\}$ incident to the leaf. Since G^t is a subgraph of G_I , this arc corresponds to an arc $\gamma \in I$, and this arc is either (j, \bar{i}) , or (\bar{i}, j) . In the first case, we set $f_\gamma = -s_{\bar{i}}^t$, in the second we set $f_\gamma = s_{\bar{i}}^t$.
 2. We eliminate from G^t the node \bar{i} and the incident arc $\{j, \bar{i}\}$, thus getting a graph G^{t+1} (which clearly is a tree).
 3. We further convert s^t into s^{t+1} as follows: for every node k of G^{t+1} which is distinct from j , we set $s_k^{t+1} = s_k^t$, and for the node j we set $s_j^{t+1} = s_j^t + s_{\bar{i}}^t$; note that the sum of entries in the resulting vector s^{t+1} is the same as the similar sum for s^t , that is, is 0.
 4. Step t is completed; when $t < m-1$, we pass to step $t+1$, otherwise we terminate.

Note that upon termination, we have at our disposal the entries f_γ for all $\gamma \in I$. Setting $f_\gamma = 0$ for $\gamma \notin I$, we get a flow f ; it is immediately seen that this flow satisfies $Af = b$, that is, f is the tree solution we are looking for.

Illustration: Let us illustrate the above algorithm for finding a tree solution. Our data are as follows:

- G is the 4-node oriented graph shown on figure 5.1 (right);
- $I = \{(1, 3), (2, 3), (3, 4)\}$ (these arcs clearly form a tree when their directions are ignored);
- $s = [1; 2; 3; -6]$.

The algorithm works as follows:

- $G^1 = G_I$ is the undirected graph with the nodes 1,2,3,4 and the arcs $\{1, 3\}, \{2, 3\}, \{3, 4\}$, and $s^1 = [1; 2; 3; -6]$;
- At the first step, we choose a leaf in G^1 , let it be the node 2, and the unique arc $\{2, 3\}$ incident in G^1 to this node. The corresponding arc in G is $\gamma = (2, 3)$. We set $f_{2,3} = s_2^1 = 2$, eliminate from G^1 the node 2 and the arc $\{2, 3\}$, thus obtaining $G^2 = (\{1, 3, 4\}, \{\{1, 3\}, \{3, 4\}\})$, and set $s_1^2 = 1$, $s_3^2 = 2 + 3 = 5$, $s_4^2 = -6$. The first step is completed.
- At the second step, we choose in G^2 a leaf, let it be the node 4, and the unique arc $\{3, 4\}$ incident to this node; the corresponding arc in G is $(3, 4)$. We set $f_{3,4} = -s_4^2 = 6$, eliminate from G^2 the node 4 and the arc $\{3, 4\}$, thus obtaining $G^3 = (\{1, 3\}, \{\{1, 3\}\})$, and set $s_1^3 = s_1^2 = 1$, $s_3^3 = s_3^2 + s_4^2 = -1$. The second step is completed.
- At the third step, we take a leaf in G^3 , let it be the node 3, and the arc $\{1, 3\}$ incident to this node. The associated arc in G is $(1, 3)$ and we set $f_{1,3} = -s_3^3 = 1$.

Finally, we augment the entries $f_{2,3} = 2$, $f_{3,4} = 6$, $f_{1,3} = 1$ we have built with $f_{1,2} = 0$, thus getting a flow satisfying the conservation law, the vector of external supplies being s , and vanishing outside of the arcs from I .

5.3.3 Reduced costs

As we remember, at every step of the Primal Simplex method we have in our disposal a base I of A along with the associated basic solution f^I , and the vector c^I of *reduced costs* of the form $c - A^T \lambda_I$, where λ_I is uniquely defined by the requirement that the reduced costs with indexes from I are equal to 0. In the case of problem (5.3.2), it is convenient to write the reduced costs in the equivalent form $c - P^T \lambda$, where $\lambda \in \mathbf{R}^m$ is normalized by the requirement $\lambda_m = 0$. Recalling the structure of P , the requirements specifying the reduced cost c^I become

$$\begin{aligned} (c^I)_{ij} &:= c_{ij} + \lambda_i - \lambda_j, \quad (i, j) \in \mathcal{E} & (a) \\ c_{ij} &= \lambda_j - \lambda_i, \quad (i, j) \in I & (b) \end{aligned} \tag{5.3.3}$$

We are about to point out a simple algorithm for building the required vector λ . Recall that the bases I we are exactly the collections of $m - 1$ arcs of G which form a tree after their directions are ignored. Given such a collection, a byproduct of the algorithm for building the associated feasible solution is the collection of subgraphs $G^t = (\mathcal{N}^t, \mathcal{E}^t)$, $t = 1, \dots, m - 1$, of G_I , every one of the subgraphs being a tree, such $G^1 = G_I$ and for every $t < m - 1$ G^{t+1} is obtained from G^t by eliminating a leaf node \bar{i}_t of G^t along with the unique arc $\{\bar{j}_t, \bar{i}_t\}$ of G^t which is incident to this node. It is immediately seen that every arc in G_I is of the form $\{\bar{j}_t, \bar{i}_t\}$ for certain t . Given G^t , $t = 1, \dots, m - 1$, we can build the vector λ_I of Lagrange multipliers as follows:

- [first step] G^{m-1} is a 2-node tree, let these nodes be α and β . Without loss of generality we can assume that (α, β) is an arc in I . Let us set $\bar{\lambda}_\alpha = 0$, $\bar{\lambda}_\beta = c_{\alpha\beta}$, thus ensuring $c_{\alpha\beta} = \bar{\lambda}_\beta - \bar{\lambda}_\alpha$.

- [ℓ -th step, $m - 1 \geq \ell \geq 2$] At the beginning of step ℓ we already have in our disposal the Lagrange multipliers $\bar{\lambda}_i$ associated with the nodes i of $G^{m-\ell+1}$, and these multipliers satisfy the relations $c_{ij} = \bar{\lambda}_j - \bar{\lambda}_i$ for all arcs $\gamma \in I$ which link the nodes of $G^{m-\ell+1}$. At the step, we take the only node, $\bar{i} = \bar{i}_{m-\ell}$, of the graph $G^{m-\ell}$ which is not a node of $G^{m-\ell+1}$, and identify the (unique!) incident to this node arc $\{\bar{j}, \bar{i}\}$ in $G^{m-\ell}$; note that by construction of the graphs G^t , \bar{j} is a node of $G^{m-\ell+1}$, so that the Lagrange multiplier $\bar{\lambda}_{\bar{j}}$ is already defined. Now, the arc γ in I associated with the arc $\{\bar{j}, \bar{i}\}$ of $G^{m-\ell}$, is either (\bar{j}, \bar{i}) , or (\bar{i}, \bar{j}) . In the first case, we set $\bar{\lambda}_{\bar{i}} = \bar{\lambda}_{\bar{j}} + c_{\bar{i}, \bar{j}}$, and in the second case, we set $\bar{\lambda}_{\bar{i}} = \bar{\lambda}_{\bar{j}} - c_{\bar{i}, \bar{j}}$, thus ensuring in both cases that c_γ is the difference of the Lagrange multipliers associated with the end- and the start-nodes of γ . As a result of step ℓ , we have defined the multipliers $\bar{\lambda}_i$ for all nodes of $G^{m-\ell}$, and have ensured, for every arc $\gamma \in I$ linking the nodes from $G^{m-\ell}$, that the transportation cost c_γ of this arc is the difference of the multipliers associated with the end- and the start-node of the arc. When $\ell < m - 1$, we pass to the next step, otherwise we terminate.

As a result of the outlined algorithm, we get a vector $\bar{\lambda}$ of multipliers associated with the nodes of G and satisfying the requirements (5.3.3.b). Subtracting from all entries of $\bar{\lambda}$ the quantity $\bar{\lambda}_n$, we keep (5.3.3.b) intact and meet the normalization requirement $\lambda_n = 0$ on the multipliers, thus obtaining λ_I .³

Illustration: Let us equip the graph G depicted on figure 5.1 (right) with transportation costs $c_{1,2} = 1$, $c_{2,3} = 4$, $c_{1,3} = 6$, $c_{3,4} = 8$ and compute the vector of reduced costs, the base I being the same set of arcs $\{(1,3), (2,3), (3,4)\}$ we used when illustrating the algorithm for building basic solutions, see p. 175. The corresponding subgraphs of G_I are $G^1 = (\{1,2,3,4\}, \{\{1,3\}, \{2,3\}, \{3,4\}\})$, $G^2 = (\{1,3,4\}, \{\{1,3\}, \{3,4\}\})$, $G^3 = (\{1,3\}, \{\{1,3\}\})$. We start with looking at G^3 and setting $\bar{\lambda}_1 = 0$, $\bar{\lambda}_3 = c_{1,3} = 6$. At the next step we look at G^2 ; the node of G^2 which is not in G^3 is 2, and we set $\bar{\lambda}_2 = \bar{\lambda}_3 - c_{2,3} = 6 - 4 = 2$. At the last step, we look at the graph $G^1 = G_I$; the node of this graph which is not in G^2 is 4, and we set $\bar{\lambda}_4 = \bar{\lambda}_3 + c_{3,4} = 6 + 8 = 14$. The Lagrange multipliers (before normalization) form the vector $\bar{\lambda} = [0; 2; 6; 14]$, and after normalization $-\lambda = \lambda_I = [-14; -12; -8; 0]$. The reduced costs are

$$(c^I)_{1,2} = c_{1,2} + \lambda_1 - \lambda_2 = 1 + (-14 + 12) = -1, (c^I)_{1,3} = c_{1,3} + \lambda_1 - \lambda_3 = 6 + (-14 + 8) = 0, \\ (c^I)_{2,3} = c_{2,3} + \lambda_2 - \lambda_3 = 4 + (-12 + 8) = 0, (c^I)_{3,4} = c_{3,4} + \lambda_3 - \lambda_4 = 8 + (-8 - 0) = 0.$$

Note that we could skip computation of the reduced costs associated with the arcs from I – we know in advance that they are zeros.

5.3.4 Updating basic feasible solution

We now are ready to describe a step of the Network Simplex algorithm. As we remember from the general description of the Primal Simplex algorithm, this step is as follows (in the description below, the general-case rules (in *Italics*) is accompanied by its “network flow translation” (in Roman)):

1. *At the beginning of the step, we have at our disposal the current basis I along with the associated basic feasible solution.*

At the beginning of the step, we have at our disposal a set I of $m - 1$ arcs of G which form

³in actual computations, there is no reason to care on normalization $\lambda_n = 0$ of a vector of Lagrange multipliers, since all which matters – the associated reduced costs (5.3.3.b) – depend only on the differences of the entries in λ .

a tree after their directions are ignored, along with the flow f^I which vanishes outside of the arcs from I , satisfies $Af^I = b$ and is nonnegative.

2. *At the step, we start with computing the vector of reduced costs.*

At the step, we apply algorithm presented on p. 176 to get the vector of Lagrange multipliers $\lambda \in \mathbf{R}^n$ such that

$$c_{ij} = \lambda_j - \lambda_i \quad \forall (i, j) \in I$$

and form the reduced costs

$$(c^I)_{ij} = c_{ij} + \lambda_i - \lambda_j, \quad \forall (i, j) \in \mathcal{E}. \quad (5.3.4)$$

If all the reduced costs are nonnegative, we terminate – f^I is an optimal solution to (5.3.2), and λ is the corresponding “optimality certificate” – an optimal solution to the dual problem. (Note that we are solving a minimization problem, so that optimality corresponds to non-negativity of all reduced costs). Otherwise we identify a variable with negative reduced cost; this is the non-basic variable to enter the basis.

We terminate when $c^I \geq 0$, otherwise find an arc $\bar{\gamma} = (\bar{i}, \bar{j})$ such that $(c^I)_{\bar{i}\bar{j}} < 0$.

3. *We start to increase the value of the nonbasic variable entering the basis, updating the values of the basic variables in order to maintain the equality constraints, until*
— *either one of the basic variables is about to become negative; this variable leaves the basis. In this case, we update the basis by including the variable which enters the basis and eliminating the variable which leaves it, updating accordingly the basic feasible solution, and pass to the next step of the method;*

— *or it turns out that when the variable entering the basis increases, no basic variables are about to become negative. In this case, we have found a recessive direction of the feasible domain X along which the objective decreases; this direction certifies that the problem is unbounded, and we terminate. Recall that according to the general theory of the Primal Simplex method, the recessive direction in question generates an extreme ray in $\text{Rec}(X)$. The “network translation” of the latter rules is as follows. There are two possibilities:*

A. *The “index” – the arc $\bar{\gamma} = (\bar{i}, \bar{j})$ – of the variable $f_{\bar{\gamma}}$ which enters the basis is not the arc inverse to one of the arcs in \mathcal{I} ;*

B. *The arc $\bar{\gamma}$ is inverse to one of the arcs from \mathcal{I} .*

Case A: In this case, the arc $\bar{\gamma}$ induces a new arc, $\{\bar{i}, \bar{j}\}$, in the undirected graph G_I , this converting this tree into a new graph G_I^+ which is not a tree anymore. By Theorem 5.1.1, G_I^+ has exactly one cycle, which includes this new arc $\{\bar{i}, \bar{j}\}$. “Lifting” this cycle to G , we get a cycle C in G – a sequence $i_1, \dots, i_t = i_1$ of nodes of G such that

- the nodes i_1, \dots, i_{t-1} are distinct from each other,
- $i_1 = \bar{i}, i_2 = \bar{j}$, so that i_1 and i_2 are linked by the arc $\bar{\gamma}$, and
- every other pair of consecutive nodes $i_2, i_3, i_3, i_4, \dots, i_{t-1}, i_t$ in our sequence $i_1, \dots, i_t = i_1$ is linked by an arc from I . For a pair of consecutive nodes i_s, i_{s+1} , $2 \leq s < t$, the corresponding arc is either (i_s, i_{s+1}) (“forward arc”), or (i_{s+1}, i_s) (“backward arc”).

Let Γ be the collection of arcs forming the above cycle C ; one of them is $\bar{\gamma}$, and it is a forward arc of the cycle, and the remaining arcs belong to I , some of them being forward,

and some of them being backward. Consider the flow h given by

$$h_\gamma = \begin{cases} +1, & \gamma \in \Gamma \text{ is a forward arc of } C \\ -1, & \gamma \in \Gamma \text{ is a backward arc of } C \\ 0, & \text{all other cases} \end{cases}$$

It is immediately seen that $Ph = 0$, whence $Ah = 0$ as well, whence, in turn, $A(f^I + th) = b := [s_1; \dots; s_{n-1}]$ for all t , that is, $f^I(t) := f^I + th$ is a flow which satisfies the equality constraints in (5.3.2). When $t = 0$, this flow is feasible, and when t grows, starting with 0, the cost of this flow decreases. Indeed, the change in the cost $c^T f^I(t) - c^T f^I$ is the same as when the original costs c are replaced with the reduced costs c^I ⁴. Since the reduced costs corresponding to all arcs in C except for the arc $\bar{\gamma}$ are zero, we conclude that $c^T f^I(t) - c^T f^I = [c^I]^T f^I(t) - [c^I]^T f^I = [c^I]^T [th] = t[c^I]^T h = tc_{\bar{\gamma}}^I h_{\bar{\gamma}} = tc_{\bar{\gamma}}^I$ (since $h_{\bar{\gamma}} = 1$ by construction of h ; note that $\bar{\gamma}$ is a forward arc in C). Since $C_{\bar{\gamma}}^I < 0$, we see that the direction h is a direction of improvement of the objective: when t is positive, $c^T f^I(t) < c^T f^I$.

Now, two cases are possible:

A.1. $h \geq 0$ (this is so if and only if all arcs of G comprising the cycle C are forward). In this case, $f^I(t)$ is a feasible solution of (5.3.2) for all $t > 0$, and as $t \rightarrow \infty$, the cost of this feasible solution goes to $-\infty$, meaning that the problem is below unbounded. In this case we terminate with a certificate h of unboundedness in our hands.

A.2. Some entries in h are negative (this happens when C includes backward arcs). In this case, when increasing t starting from $t = 0$, the flow $f^I(t)$ eventually loses nonnegativity. Since the $\bar{\gamma}$ -component of the flow $f^I(t)$ is equal to t , the entries in the flow which can eventually become negative are among those with indexes in I . We can easily compute the largest $t = \bar{t}$ for which $f^I(t)$ still is nonnegative:

$$\bar{t} = \min\{f_\gamma^I : \gamma \in I \text{ is a backward arc of } C\}.$$

In the flow $f^I(\bar{t})$, one (or more) of components of $f_\gamma^I(\bar{t})$ with indexes $\gamma \in I$ become zero. We take one of the corresponding arcs, let it be denoted $\tilde{\gamma}$, and claim that it leaves the basis, while $\bar{\gamma}$ enters it, so that the updated basis is $I^+ = (I \setminus \{\tilde{\gamma}\}) \cup \{\bar{\gamma}\}$, and the new basic feasible solution is $f^I(\bar{t})$. Observe that I^+ indeed is a basis.

This observation (which is readily given by the general theory of the Primal Simplex method; recall that we are just “translating” this method to the particular case of network problem (5.3.2)) can be justified “from scratch,” namely, as follows: the undirected counterpart G_{I^+} of the graph obtained from G when eliminating all arcs except for those from I^+ is obtained from the tree G_I as follows:

— we first add to G_I a new arc $\{\bar{i}, \bar{j}\}$ (it is induced by $\bar{\gamma}$); the resulting graph G_I^+ has m arcs and a unique cycle induced by the cycle C in G ;

⁴This fact is given by the theory of the Primal Simplex method: on the set of solutions to the system of equality constraints of a problem in the standard form, the objective given by the original cost vector differs by a constant from the objective given by the vectors of reduced costs, so that the changes in both objectives when passing from one solution satisfying the equality constraints to another solution with the same property are equal to each other.

— to get G_{I+} , we eliminate from the graph G_I^+ an arc which belongs to the unique cycle of G_I^+ , thus getting a graph with $m - 1$ nodes. The arc we eliminate from G_I^+ is induced by the arc $\tilde{\gamma}$ in C and is different from the arc $\{\bar{i}, \bar{j}\}$. Since G_I^+ clearly is connected along with G_I , and eliminating from a connected graph an arc belonging to a cycle, we preserve connectivity, G_{I+} is a connected graph with m nodes and $m - 1$ arcs and thus is a tree (Theorem 5.1.1), as claimed.

Thus, in the case of A.2 we convert the current basis I and the associated basic feasible solution f^I into a new basis I^+ and the corresponding new basic feasible solution $f^{I^+} = f_{\bar{t}}^I$, and can pass to the next step of the algorithm.

Remark. Note that in the case of $\bar{t} > 0$, the cost of the new basic feasible solution is strictly smaller than the cost of the old solution, in full accordance with the general theory of the Primal Simplex method. It may happen, however, that $\bar{t} = 0$, in which case the basic feasible solution remains intact, and only the basis changes; this, in full accordance with the general theory, can happen only when the basic feasible solution f^I we are updating is degenerate – has less than $m - 1$ positive entries.

Case B: Recall that this is the case when the arc $\bar{\gamma} = (\bar{i}, \bar{j})$ with negative reduced cost $c_{\bar{\gamma}}^I$ – the index of the variable which enters the basis, in the general Simplex terminology – is inverse to one of the arcs from I . In this case we act in the same fashion as in the case A, although our life becomes simpler. The analogy of the cycle C is now the loop $\bar{\gamma} = (\bar{i}, \bar{j})$, $\hat{\gamma} = (\bar{j}, \bar{i})$ (recall that we are in the situation when the second arc in this loop belongs to I). The flow h satisfying $Ph = 0$ is now the flow with exactly two nonzero components, $h_{\bar{\gamma}}$ and $h_{\hat{\gamma}}$, both equal to 1; and since $c_{\bar{\gamma}}^I < 0$, $c_{\hat{\gamma}}^I = 0$, adding to f^I a positive multiple th of the “circulation” h , we, same as in the case of A, reduce the cost of the flow, keeping it feasible; thus, we have discovered a recessive direction of the feasible set of the problem. Along this direction, the objective decreases, that is, we can terminate with a certificate of unboundedness in our hands.

The description of a step in the Network Simplex algorithm as applied to the uncapacitated network flow problem is completed.

Illustration: Let us carry out a step of the Network Simplex algorithm as applied to the directed graph depicted on figure 5.1 (right), the external supplies and the transportation costs being as in the illustrations on pp. 176 and 177, that is:

$$s = [1; 2; 3; -6]; \quad c_{1,2} = 1, c_{2,3} = 4, c_{1,3} = 6, c_{3,4} = 8.$$

Let the current basis be $I = \{(1, 3), (2, 3), (3, 4)\}$; the associated graph G_I is the undirected graph with nodes 1, 2, 3, 4 and arcs $\{1, 3\}, \{2, 3\}, \{3, 4\}$. The corresponding basic solution was computed in illustration on p. 176, it is

$$f_{1,2}^I = 0, f_{1,3}^I = 1, f_{2,3}^I = 2, f_{3,4}^I = 6;$$

as we see, this solution is feasible. The reduced costs associated with the basis I were computed in illustration on p. 177; they are

$$(c^I)_{1,2} = -1, (c^I)_{1,3} = 0, (c^I)_{2,3} = 0, (c^I)_{3,4} = 0.$$

The reduced cost associated with the arc $(1, 2)$ is negative, meaning that the solution f^I is nonoptimal. We enter the arc $\bar{\gamma} = (1, 2)$ into the basis (that is, the variable $f_{1,2}$ should

become a basic variable). When adding to G_I the non-oriented arc $\{1, 2\}$ associated with the oriented arc $\bar{\gamma}$ in G , we get a graph G_I^+ which is non-oriented counterpart of G ; in full accordance with our theory, it has a single cycle $1, 2, 3, 1$. The corresponding cycle C in G is $1, (1, 2), 2, (2, 3), 3, (1, 3), 1$; the arcs $(1, 2)$ and $(2, 3)$ are forward, and the arc $(1, 3)$ is backward. We are in Case A; the improving direction h is $h_{1,2} = 1, h_{1,3} = -1, h_{2,3} = 1, h_{3,4} = 0$; as it should be, this direction satisfies $Ph = 0$ (that is, it is a flow meeting the conservation law, the external supplies being zero). We now add a nonnegative multiple th of the flow h to our “old” basic feasible flow f^I , choosing the largest possible t for which the updated flow is nonnegative. Looking at f^I and h , we get $t = 1$; the variable which leaves the basis is $f_{1,3}$, the variable which enters the basis is $f_{1,2}$ (in terms of the indexes: the arc which should be added to I is $\bar{\gamma} = (1, 2)$, the arc which leaves I is $\tilde{\gamma} = (1, 3)$). The new basis and basic feasible solution are

$$I^+ = \{(1, 2), (2, 3), (3, 4)\}, f_{1,2}^{I^+} = 1, f_{1,3}^{I^+} = 0, f_{2,3}^{I^+} = 2, f_{3,4}^{I^+} = 6.$$

The step is completed.

Let us carry out the next step of the algorithm. To this end let us compute the reduced costs associated with our new basis I^+ . Applying algorithm presented on p. 177, we get

$$\begin{aligned} \lambda_1 &= -13, \lambda_2 = -12, \lambda_3 = -8, \lambda_4 = 0, \\ (c^{I^+})_{1,2} &= (c^{I^+})_{2,3} = (c^{I^+})_{3,4} = 0, (c^{I^+})_{1,3} = c_{1,3} + \lambda_1 - \lambda_3 = 6 + (-13 + 8) = 1. \end{aligned}$$

The reduced costs are nonnegative, meaning that the flow f^{I^+} is optimal.

5.3.5 Network Simplex Algorithm: Summary and Remarks

Summary of the algorithm. We have described in details the “building blocks” of the network-oriented implementation of the Primal simplex method. When put together, we get an algorithm which can be summarized as follows:

1. At the beginning of a step, we have at our disposal current basis I , which is the set of $m - 1$ arcs in G which form a tree after their directions are ignored, along with the corresponding basic feasible solution f^I ; this is a feasible flow such that $f_{\gamma}^I = 0$ for all arcs $\gamma \notin I$.
2. At the step, we
 - (a) use the algorithm presented on p. 177 to compute the Lagrange multipliers $\lambda_1, \dots, \lambda_m$ such that

$$c_{ij} = \lambda_i - \lambda_j \quad \forall (i, j) \in I$$

and then compute the reduced costs

$$(c^I)_{ij} = c_{ij} + \lambda_i - \lambda_j, (i, j) \in \mathcal{E}.$$

The reduced costs associated with the arcs $\gamma \in I$ are zero. If all remaining reduced costs are nonnegative, we terminate – f^I is an optimal solution to (5.3.2), and the vector $\lambda^I = [\lambda_1 - \lambda_n; \dots; \lambda_{m-1} - \lambda_m]$ is the optimal solution to the dual problem.

- (b) If there are negative reduced costs, we pick one of them, let it be c_{ij}^I , and add to I the arc $\bar{\gamma} = (\bar{i}, \bar{j})$ (“variable $f_{\bar{\gamma}}$ enters the basis”). We extend (it is always possible) the arc $\bar{\gamma}$ by arcs from I to get a loop $i_1 := \bar{i}, \gamma_1 := \bar{\gamma}, i_2 := \bar{j}, \gamma_2, i_3, \gamma_3, \dots, \gamma_{t-1}, i_t = \bar{i}$; here $\gamma_2, \dots, \gamma_{t-1}$ are distinct arcs from I , the nodes $i_1 = \bar{i}, i_2 = \bar{j}, i_3, \dots, i_{t-1}$ are distinct from each other, and for every $s < t$ γ_s is either the arc (i_s, i_{s+1}) (“forward arc”), or

the arc (i_{s+1}, i_s) ("backward arc"). This loop gives rise to a flow h which is equal to 1 at every forward arc and equal to -1 in every backward arc of the loop, and vanishes in all arcs not belonging to the loop; this flow satisfies the relation $Ph = 0$ and $[c^I]^T h = c_{\bar{\gamma}}^I < 0$. It follows that a flow of the form $f^I(t) := f^I + th$ with $t \geq 0$ satisfies the flow conservation law: $Pf^I(t) = s$, and its cost strictly decreases as t grows.

- (c) It may happen that the flow $f^I(t)$ remains nonnegative for all $t \geq 0$. In this case we have found a ray in the feasible set along which the objective tends to $-\infty$, meaning that the problem is unbounded; if it happens, we terminate, h being the unboundedness certificate.

An alternative is that some of the entries in $f^I(t)$ decrease as t increases; this clearly can happen only for the entries corresponding to arcs from I (since the only other entry in $f^I(t)$ which is not identically zero is the entry indexed by $\bar{\gamma}$, and this entry is equal to t (recall that $\bar{\gamma}$, by construction, is a forward arc in the above loop, and thus $h_{\bar{\gamma}} = 1$) and thus increases with t). We find the largest value \bar{t} of t such that the flow $f^I(\bar{t})$ is nonnegative, and eliminate from I an arc $\hat{\gamma}$ where the flow $f^I(t)$ is "about to become negative" at $t = \bar{t}$ (i.e., $\hat{\gamma}$ is such that the corresponding component of $f^I(t)$ decreases with t and becomes 0 when $t = \bar{t}$). We set $I^+ = [I \cup \{\bar{\gamma}\}] \setminus \{\hat{\gamma}\}$; this is our new basis (and it indeed is a basis), the corresponding basic feasible solution being the flow $f^{I^+} = f^I(\bar{t})$, and loop to the next step of the algorithm.

Remarks. A. Correctness and finite termination. The Network PSM is just an adaptation of the general-purpose PSM to the special case of uncapacitated Network Flow problem (5.3.2); as such, it inherits the fundamental properties of the PSM:

- the only possibilities to terminate are
 - either to produce an optimal basic feasible solution to the problem along with the optimality certificate — a feasible solution to the dual problem which, taken along with the primal solution, satisfies the complementary slackness condition and thus is an optimal solution to the dual problem,
 - or to detect that the problem is unbounded and to produce the corresponding certificate.
- the method is monotone — as a result of a step, the value of the objective either decreases, or remains the same. The latter option takes place only if the basic feasible solution the step starts with is degenerate — has less than $m - 1$ positive entries. If there are no degenerate feasible solutions at all, the method terminates in finite time. There are also examples which show that, same as in the case of a general-purpose PSM, in the presence of degenerate solutions the Network PSM can loop forever, unless an appropriate care of the "ties" in the pivoting rules is taken.

B. Oriented cycles of negative cost. The unboundedness certificate, if any, is an oriented cycle in G with negative cost, that is, a collection of t arcs $(i_1, i_2), (i_2, i_3), \dots, (i_t, i_1)$ such that the sum of the associated reduced costs is negative. Now observe that from (5.3.4) it follows that *for every oriented cycle and for every basis I of (5.3.2), the sum of reduced costs of all arcs of the cycle is equal to the sum of the original costs of the arcs*. It follows that the certificate of unboundedness produced by the Network PSM is a oriented cycle of negative total cost. It is also clear that whenever a feasible problem (5.3.2) admits an oriented cycle of negative total cost, the problem is unbounded.

C. Integrality. From the description of the Network PSM it follows that *all arithmetic operations used in the computations are additions, subtractions and multiplications; no divisions*

are involved. Therefore when the vector of external supplies is integral, so is the optimal solution (if any) reported by the Network PSM – the fact already known to us from Proposition 5.3.1. We can augment this statement by noting that when all costs c_{ij} are integral, so are all reduced costs and the associated λ_i 's (see (5.3.4)) and, in particular, the optimal dual solution (if any) returned by the algorithm is integral – this observation is readily given by algorithm for computing reduced costs presented in section 5.3.3, see p. 176.

Needless to say, absence of divisions implies that in the case of integral data all computations in the Network PSM are computations with integral operands and results, which eliminates a lot of numerical issues related to rounding errors⁵.

D. Getting started. We did not explain yet how to initialize the Network PSM – where from to take the initial basic feasible solution. The simplest way to do it is as follows. Let us augment the m -vertex graph G by an additional node, let its index be $m + 1$, and m additional artificial arcs, namely, as follows. For every original node i with nonnegative external supply, we add to the graph the arc $(i, m + 1)$, and for every original node i with negative external supply – the arc $(m + 1, i)$. Finally, we assign the new node $m + 1$ with zero external supply. For the extended graph, finding initial basic feasible solution is trivial: the corresponding basis I is just the basis comprised of the m artificial arcs⁶, and the solution is to send s_i units of flow from node i to node $m + 1$ along the arc $(i, m + 1)$, when s_i is ≥ 0 , and $-s_i$ units of flow through the arc $(m + 1, i)$, when s_i is negative. Now, it is easily seen that if the original problem is feasible and the transportation costs for the added m arcs are large enough, every optimal solution to the augmented problem will induce zero flows in the artificial — “expensive” — arcs and thus will be an optimal solution to the problem of actual interest.

5.4 Capacitated Network Flow Problem

In this section we present a modification of the Network PSM aimed at solving the *capacitated Network Flow problem* which is obtained from (5.3.2) by assuming that some of the arcs have finite capacities, that is, the flows in these arcs are subject to upper bounds. In fact, it makes sense to consider a slightly more general situation where the flows in the arcs are subject to both lower and upper bounds, so that the problem reads

$$\min_f \{c^T f : Af = b, u_\gamma \geq f_\gamma \geq \ell_\gamma, \gamma \in \mathcal{E}\}, \quad (5.4.1)$$

where, same as in (5.3.2), A is the $(m - 1) \times n$ matrix obtained by eliminating the last row in the incidence matrix P of a m -node graph G with the set of arcs \mathcal{E} , and b is the “truncation” $[s_1; \dots; s_{m-1}]$ of the vector of external supplies s , $\sum_{i=1}^m s_i = 0$. As about the bounds u_γ , ℓ_γ , we assume that

B.1: some of ℓ_γ are reals, and some can be equal to $-\infty$, similarly, some of u_γ are reals, and some are $+\infty$;

B.2: $\ell_\gamma < u_\gamma$ for all γ (“no arc flows are fixed in advance”), and

B.3: for every γ , either ℓ_γ , or u_γ , or both these quantities are reals (“no free arc flows”).

⁵It should be mentioned, however, that without additional precautions the method may suffer from “integral overflows” – some intermediate results can become too large to be stored in a computer as integers.

⁶Note that our new graph has $m + 1$ nodes, so that the basis should contain m arcs which form a tree after their directions are ignored; this is exactly the case with the proposed set of arcs.

We also keep our initial assumption that G is connected; this assumption, as we remember, implies that the rows of A are linearly independent.

5.4.1 Preliminaries: Primal Simplex Method with Bounds on Variables

When presenting the Network PSM for the capacitated Network Flow problem, it makes sense to start with the version of the general-purpose PSM aimed at handling bounds on the variables. Thus, consider a LO program

$$\text{Opt} = \min_x \{c^T x : Ax = b, \ell_j \leq x \leq u_j, 1 \leq j \leq n\}, \quad (5.4.2)$$

where for every j either ℓ_j , or u_j , or both these quantities are finite, and $\ell_j < u_j$ for all j . As about A , we assume that this is an $m \times n$ matrix with linearly independent rows.

Problem (5.4.2) is *not* in the standard form. One option to handle the problem via the PSM is to convert it into the standard form and to apply the method to the resulting problem. However, as far as the efficiency of the computational process is concerned, this option is not the best one; it is better to adjust the PSM to (5.4.2), which, as we shall see, requires just minor and mostly terminological modifications of the method.

Bases and basic solutions to (5.4.2)

The feasible set of (5.4.2) clearly does not contain lines; thus, if the problem is solvable, it admits a solution which is a vertex of the feasible set $X = \{x : Ax = b, \ell \leq x \leq u\}$. As in the basic version of the method, the PSM as applied to (5.4.2) travels along the vertices, and our first step is to describe these vertices. By algebraic characterization of extreme points, a point $v \in X$ is a vertex of X iff among the constraints defining X and active at v (i.e., satisfied at v as equalities) there are $n = \dim x$ constraints with linearly independent vectors of coefficients. Part of these m active constraints with independent vectors of coefficients, say, $m' \leq m$ of them, are the equality constraints $a_p^T x = b_p$, $p \in P$, and $n - m'$ remaining constraints in this group come from the bounds. Since $\ell_j < u_j$, the lower and the upper bounds on the same variable cannot become active simultaneously; thus, $n - m'$ entries in v should be on their upper or lower bounds, let the indexes of these constraints form a set J . Since the $n \times n$ matrix which we get by augmenting the rows a_p^T , $p \in P$, with the rows of the unit matrix corresponding to the entries of v which are at their bounds should be nonsingular, we conclude, same as in the case of the basic PSM, that *the columns of A with indexes from $I' := \{1, \dots, n\} \setminus J$ are linearly independent*. Since A is of rank m , we conclude that cardinality of I' is at most m , and I' can be extended to a basis I of A . Thus,

every vertex v of the feasible set X of (5.4.2) can be associated with a basis I of A (a set of m distinct indexes from $\{1, \dots, n\}$ such that the columns of A with these indexes are linearly independent) in such a way that every entry v_i in v with index outside of I is either ℓ_i , or u_i .

Note that given a basis I and setting every entry in x with non-basic index to ℓ_i or to u_i , there is exactly one option to define the “basic” entries in x — those with indexes from I — which results in a vector satisfying the equality constraints in (5.4.2); specifically, the basic part of x should be

$$x_I = A_I^{-1} [b - \sum_{i \notin I} x_i A_i].$$

The resulting solution x^I is called the *basic solution* associated with basis I and the way in which we set the non-basic entries in x^I – those with indexes outside of I – to the values ℓ_i and u_i . Note that feasibility of a basic solution x^I depends solely on what are the basic (those with indexes from I) entries in this solution: the solution is feasible iff these entries are between the corresponding bounds ℓ_i, u_i .

The bottom line of our discussion is as follows:

(!) Extreme points of the feasible set of (5.4.2) are exactly the *basic feasible solutions*, that is, the just defined basic solutions which happen to be feasible.

This conclusion resembles pretty much the similar conclusion for the standard form LO's. The only difference is that in the standard case a basic solution is uniquely defined by the basis, while now it is uniquely defined by the basis *and* the way in which we set the non-basic entries to their upper and lower bounds.

Reduced costs

Given a basis I , we define the associated vector c^I of reduced costs exactly as in the case of a standard form problem, that is, as

$$c^I = c - A^T A_I^{-T} c_I, \quad (5.4.3)$$

where c_I is the m -dimensional vector comprised of the entries in c with indexes from I . In other words, c^I is obtained from c by adding a linear combination of rows of A , and this combination is chosen in such a way that the basic entries in c^I are zeros. We clearly have $c^T x = [c^I]^T x$ for all x with $Ax = b$, or, equivalently,

$$Ax' = Ax'' = b \Rightarrow c^T [x' - x''] = [c^I]^T [x' - x'']. \quad (5.4.4)$$

Let us make the following observation:

Lemma 5.4.1 *Let I be a basis, x^I be an associated basic feasible solution (that is, x^I is feasible and non-basic entries in x^I sit on the bounds), and c^I be the vectors of reduced costs associated with I . Then the condition*

$$\forall i \notin I : \text{ either } (x_i^I = \ell_i \text{ and } c_i^I \geq 0), \text{ or } (x_i^I = u_i \text{ and } c_i^I \leq 0) \quad (5.4.5)$$

is sufficient for x^I to be optimal.

Proof. The fact can be easily derived from considering the dual problem, but we prefer a self-contained reasoning as follows: since x^I is feasible, all we need is to verify that if y is a feasible solution, then $c^T x^I \leq c^T y$. By (5.4.4) we have $c^T [y - x^I] = [c^I]^T [y - x^I] = \sum_{i \notin I} c_i^I [y_i - x_i^I]$ (we have taken into account that $c_i^I = 0$ when $i \in I$). For $i \notin I$ we have
— either $x_i^I = \ell_i$, $y_i \geq \ell_i$ and $c_i^I \geq 0$,
— or $x_i^I = u_i$, $y_i \leq u_i$ and $c_i^I \leq 0$,
and in both cases $c_i^I [y_i - x_i^I] \geq 0$, whence $\sum_{i \notin I} c_i^I [y_i - x_i^I] \geq 0$. □

A step of the algorithm

We are ready to describe a step of the PSM as applied to (5.4.2). At the beginning of the step, we have at our disposal a basis I along with an associated *feasible* basic solution x^I and the vector of reduced costs c^I . At the step, we act as follows:

1. We check whether x^I, c^I satisfy the sufficient condition for optimality (5.4.5). If it is the case, we terminate, x^I being the resulting optimal solution and c^I being the optimality certificate.
2. If (5.4.5) is not satisfied, we identify a non-basic index j such that either
 - Case A: $x_j^I = \ell_j$ and $c_j^I < 0$, or
 - Case B: $x_j^I = u_j$ and $c_j^I > 0$.

In the case of A, we proceed as follows: we define a parametric family $x^I(t)$ of solutions by the requirements that $x_j^I(t) = \ell_j + t$, $Ax^I(t) = b$ and $x_k^I(t) = x_k^I(t)$ for all non-basic entries with indexes k different from j . We clearly have $x^I(0) = x^I$; as $t \geq 0$ grows, the entries $x_k^I(t)$ with indexes $k \in I \cup \{j\}$ somehow vary, while the remaining entries stay intact, and we have $Ax^I(t) = b$ for all t . Note that these requirements specify $x^I(t)$ in a unique fashion, completely similar to what we have in the case of a standard form problem:

$$x^I(t) = x^I - tA_I^{-1}A_j.$$

Observe that the objective, as evaluated at $x^I(t)$, strictly improves as t grows:

$$c^T[x^I(t) - x^I] = [c^I]^T[x^I(t) - x^I] = \sum_{i \in I} \underbrace{c_i^I}_{=0} [x_i^I(t) - x_i^I] + \underbrace{c_j^I}_{<0} t + \sum_{i \notin I \cup \{j\}} \underbrace{c_i^I [x_i^I(t) - x_i^I]}_{=0}.$$

Now, when $t = 0$, $x^I(t) = x^I$ is feasible. It may happen that $x^I(t)$ remains feasible for all $t > 0$; in this case, we terminate with the claim that the problem is unbounded. An alternative is that eventually some entries $x_i^I(t)$ leave the feasible ranges $[\ell_i, u_i]$; this, of course, can happen only with the entries which do depend on t (those are the entry with index j and those of the basic entries for which the corresponding coordinates in $A_I^{-1}A_j$ is nonzero). We can easily find the largest $t = \bar{t}$ for which $x^I(t)$ still is feasible, but one or more of the coordinates in $x^I(\bar{t})$ is about to become infeasible. Denoting by i the index of such a coordinate, we set $I^+ = [I \cap \{j\}] \setminus \{i\}$, $x^{I^+} = x^I(\bar{t})$. It is immediately seen that I^+ is a basis, and x^{I^+} is an associated basic feasible solution, and we pass to the next step.

In the case of B, our actions are completely similar, with the only difference that now, instead of requiring $x_j^I(t) = \ell_j + t$, we require $x_j^I(t) = u_j - t$.

Note that the construction we have presented is completely similar to the one in the case of a standard form program. The only new possibility we meet is that as a result of a step, the basic solution is changed, but the basis remains the same. This possibility occurs when the entry $x_i^I(t)$ which is about to become infeasible when $t = \bar{t}$ is nothing but the j -th entry (which indeed is possible when both ℓ_j and u_j are finite). In this case, as a result of a step, the basis remains intact, but one of the non-basic variables jumps from one of its bounds to another bound, and the objective is strictly improved.

Finally, observe that the presented method is monotone. Moreover, the objective strictly improves at every step which indeed changes the current basic feasible solution, which definitely is the case when this solution is nondegenerate, i.e., not all basic entries in the solution are

strictly within their bounds. What does change at a step which does not update the basic feasible solution, is the basis. These remarks clearly imply our standard conclusions on the correctness of the results reported by the method upon termination (if any) and on finiteness of the method in the nondegenerate case.

5.4.2 Network PSM for Capacitated Network Flow Problem

The network PSM for the capacitated Network Flow problem is nothing but the specialization of the just outlined PSM for solving (5.4.2) to the case of problem (5.4.1). We already have in our disposal all “network-specific” building blocks (they are inherited from the uncapacitated case), same as the blueprint of how these blocks should be assembled (see the previous section), so that all we need is just a brief summary of the algorithm. This summary is as follows.

1. At the beginning of an iteration, we have at our disposal a basis I — a collection of $m - 1$ arcs in G which form a tree when their directions are ignored — along with the corresponding basic feasible flow f^I — a feasible solution f^I to (5.4.1) such that the flows f_γ^I in the arcs distinct from those from I are at their upper or lower bounds.
2. At a step we act as follows.
 - (a) We compute the vector of reduced costs $c_{ij}^I = c_{ij}^I + \lambda_i - \lambda_j$ according to the algorithm presented in section 5.3.3, so that $c_\gamma^I = 0$ when $\gamma \in I$.
 - (b) If for every arc $\gamma \notin I$ we have either $c_\gamma^I \geq 0$ and $f_\gamma^I = \ell_\gamma$, or $c_\gamma^I \leq 0$ and $f_\gamma^I = u_\gamma$, we terminate — f^I is an optimal solution, and c^I is the associated optimality certificate.
 - (c) If we do not terminate according to the previous rule, we specify an arc $\bar{\gamma} := (\bar{i}, \bar{j}) \notin I$ such that either
 - Case A: $c_{\bar{\gamma}}^I < 0$ and $f_{\bar{\gamma}}^I = \ell_{\bar{\gamma}}$, or
 - Case B: $c_{\bar{\gamma}}^I > 0$ and $f_{\bar{\gamma}}^I = u_{\bar{\gamma}}$.
 Below we assume that we are in the case of A (our actions in the case of B are completely “symmetric”).
 - (d) Same as in the uncapacitated case, we find a loop $i_1 := \bar{i}, \gamma_1 := \bar{\gamma}, i_2 := \bar{j}, \gamma_2, i_3, \dots, i_{t-1}, \gamma_{t-1}, i_t = i_1$, where i_1, \dots, i_{t-1} are distinct nodes of G and $\gamma_2, \dots, \gamma_{t-1}$ are distinct from each other arcs from I such that either $\gamma_s = (i_s, i_{s+1})$ (forward arc), or $\gamma_s = (i_{s+1}, i_s)$ (backward arc) for every $s, 1 \leq s \leq t - 1$. We define flow h which vanishes outside of the arcs from the loop, and in the arc γ from the loop is equal to 1 or -1 depending on whether the arc is or is not a forward one. We further set $f^I(t) = f^I + th$, thus getting a flow such that

$$f^I(0) = f^I \text{ and } Af^I(\tau) = b \forall t, c^T[f^I(\tau) - f^I] = \underbrace{c_{\bar{\gamma}}}_{<0} t.$$

- (e) It may happen that the flow $f^I(t)$ remains feasible for all $t \geq 0$. In this case, we have found a feasible ray of solutions to (5.4.1) along which the objective goes to $-\infty$, and we terminate with the conclusion that the problem is unbounded. An alternative is that as $t \geq 0$ grows, some of the entries $f_\gamma^I(t)$ eventually become infeasible. In this case it is easy to identify the smallest $t = \bar{t} \geq 0$ for which $f^I(\bar{t})$ still is feasible, same as it is easy to identify an arc $\hat{\gamma}$ from the above loop such that the flow $f_{\hat{\gamma}}^I(t)$ at $t = \bar{t}$

is about to become infeasible. We add to I the arc $\bar{\gamma}$ and delete from the resulting set the arc $\hat{\gamma}$, thus getting a new basis, the corresponding basic feasible solution being $f^{I^+} = f^I(\bar{t})$, and pass to the next step.

The resulting algorithm shares with its uncapacitated predecessor all the properties mentioned on p. 182, in particular, produces upon termination (if any) an *integral* optimal flow, provided that all entries in b and all finite bounds ℓ_i, u_i are integral. To initialize the algorithm, one can use the same construction as in the uncapacitated case, with zero lower and infinite upper bounds on the flows in the artificial arcs.

Complexity of Linear Optimization and The Ellipsoid Method

Lecture 6

Polynomial Time Solvability of Linear Optimization

6.1 Complexity of LO: Posing the Question

We know that the Simplex Method equipped with an anti-cycling strategy is a *finite* algorithm assuming precise arithmetics, it solves *exactly* every LO program in *finitely many arithmetic operations*. Once upon a time this property was considered the most desirable property a computational routine can possess. However, actual computations require from a good computational routine not only to be able to solve problems, but also to do it “in reasonable time.” From practical perspective, the promise that a particular algorithm, as applied to a particular problem, will eventually solve it, but the computation will take 10^{10} years, does not worth much. At the theoretical level, the purely practical by its origin question of “how long a computation will take” is posed as investigating *complexity* of problem classes and solution algorithms. Speaking informally, the complexity is defined as follows:

1. We are interested in solving problems from certain family \mathcal{P} (e.g., the family of all LO programs in the standard form); let us call this family a *generic problem*, and particular member $p \in \mathcal{P}$ of this family (in our example, a particular LO program in the standard form) – an *instance* of \mathcal{P} . We assume that within the family, an instance is identified by its *data*, which form an array of numbers. E.g., the data of an LO in the standard form are comprised of two integers m, n – the sizes of the constraint matrix A , two linear arrays storing the entries of the objective c and the right hand side vector b , and one two-dimensional array storing the constraint matrix A . In fact, we lose nothing by assuming that the data $\text{data}(p)$ of an instance is a single one-dimensional array, i.e., a vector. E.g., in the LO case, we could start this vector with m and n , then write one by one the entries of c , then – the entries of b , and then – the entries of A , say, column by column. With this convention, given the resulting data vector, one can easily convert it into the usual representation of an LO program by two vectors and a matrix.

Similarly, we can assume that candidate solutions to instances are linear arrays – vectors (as it indeed is the case with LO).

2. Now, a solution method \mathcal{B} for \mathcal{P} can be thought of as a program for a computer. Given on input the data vector $\text{data}(p)$ of an instance $p \in \mathcal{P}$ and executing this program on this input, the computer should eventually terminate and output the vector representing the

solution of p we are looking for, or, perhaps, a valid claim “no solution exists.” E.g., in the LO situation the result should be either the optimal solution to the LO instance the algorithm is processing, if any, or the correct claim “the instance is unsolvable,” perhaps, with explanation why (infeasibility of unboundedness).

3. We now can measure the complexity $\mathcal{C}(\mathcal{B}, p)$ of \mathcal{B} as applied to an instance $p \in \mathcal{P}$ as the *running time* of \mathcal{B} as applied to the instance, that is, as the total time taken by elementary operations performed by the computer when processing the instance. Given \mathcal{B} , this complexity depends on the instance p in question, and it makes sense to “aggregate” it into something which depends only on the pair $(\mathcal{B}, \mathcal{P})$. A natural way to do it is to associate with an instance p its “size” $\text{Size}(p)$ which is a positive integer which somehow quantifies the “volume of the data” in p . For example, we can use, as the size, the number of data entries specifying the instance within \mathcal{P} , that is, the dimension of the data vector $\text{data}(p)$. Another, more realistic, as far as digital computations are concerned, way to define the size is to assume that the data entries admit finite binary representation, e.g., are integers or rationals (i.e., pairs of integers), and to define the size of an instance p as the total number of bits in the vector $\text{data}(p)$; this is called the *bit size* of p .

After the instances of \mathcal{P} are equipped with sizes, we can define the *complexity of a solution algorithm* \mathcal{B} as the function

$$\mathcal{C}_{\mathcal{B}}(L) = \sup_p \{ \mathcal{C}(\mathcal{B}, p) : p \in \mathcal{P}, \text{Size}(p) \leq L \}$$

which shows how the worst-case, over instances of sizes not exceeding a given bound L , running time of \mathcal{B} as applied to an instance, depends on L .

We then can decide which types of complexity functions are, and which are not appropriate for us, thus splitting all potential solution algorithms for \mathcal{P} into *efficient* and *inefficient*, and investigate questions like

- Whether such and such solution algorithm \mathcal{B} , as applied to such and such generic problem \mathcal{P} , is efficient? What is the corresponding complexity?
- or • Whether such and such generic problem \mathcal{P} is efficiently solvable, that is, admits an efficient solution algorithm?

A reader could argue why should we quantify complexity in the worst-case fashion, and not by the “average” or “with high probability” behavior of the algorithm. Practically speaking, a claim like “such and such algorithm solves instances of size L in time which, with probability 99.9%, does not exceed $0.1L^2$ ” looks much more attractively than the claim “the algorithm solves every instance of size L in time not exceeding $100L^3$.” the difficulty with probabilistic approach is that most often we cannot assign the data of instances with a meaningful probability distribution. think of LO: LO programs arise in an extremely wide spectrum of applications, and what is “typical” for the Diet problem modeling nutrition of chickens can be quite atypical for “the same” problem as applied to nutrition of cows, not speaking about problems coming from production planning. As a result, meaningful probabilistic approach can make sense (and indeed makes sense) only when speaking about relatively narrow problems coming from a “isolated” and well understood source. A typical alternative – to choose a data distribution on the basis of mathematical convenience – usually leads to “efficient” algorithms poorly performing in actual applications.

Polynomial time algorithms and polynomially solvable generic problems. As a matter of fact, there exists a complete consensus on what should be treated as an “appropriate complexity” — this is *polynomially* of the complexity in L , that is, the existence of a polynomial in L upper bound on this function. Thus, a solution algorithm \mathcal{B} for a generic problem \mathcal{P} is called *polynomial*, or *polynomial time*, if

$$C_{\mathcal{B}}(L) \leq cL^d$$

for fixed constants c, d and all $L = 1, 2, \dots$. A generic problem \mathcal{P} is called *polynomially solvable*, or *computationally tractable*, if it admits a polynomial time solution algorithm.

Informally, the advantage of polynomial time algorithms as compared to their most typical (and usually easy to build) alternatives, the exponential time algorithms with the complexity $\exp\{O(1)L\}$, can be illustrated as follows. Imagine that you are solving instances of certain generic problem on a computer, and then get a 10 times faster computer. If you use a polynomial time algorithm, this constant factor improvement in the hardware will result in constant *factor* increase in the size of an instance you can process in a given time, say, in one hour. In contrast to this, with an exponential algorithm, 10-fold improvement in the performance of the hardware increase the size L of an instance you can solve in one hour *only additively*: $L \mapsto L + \text{const}$.

There are deep reasons for why the theoretical translation of the informal notion “computationally tractable generic problem” is polynomial time solvability. The most important argument in favor of formalizing tractability as polynomial solvability is that with this formalization the property to be tractable becomes independent of how exactly we encode candidate solutions and data of instances by linear arrays; as a matter of fact, all natural encodings of this type can be converted one into another by polynomial time algorithms, so that the property of a problem to be tractable turns out to be independent of how exactly the data/candidate solutions are organized. Similarly, the property of an algorithm to be polynomial time is insensitive to minor details on what are the elementary operations of the computer we use. As a result, theoretical investigation of complexity can ignore “minor technical details” on how exactly we encode the data and what exactly our computer can do, thus making the investigation humanly possible.

E.g., a natural way to store the data of a multicommodity flow problem is essentially different from a natural way to store the data of the standard form representation of the same problem. Indeed, to specify a problem with N commodities on a graph with n nodes and m arcs, we need to point out the incidence matrix of the graph (mn data entries when we store the matrix as a full one), the supply of each commodity at each node (totally Nn data entries) and Nm cost coefficients; all this amounts to $N(m + n) + mn$ data entries. In the standard form representation of the same problem there are more than Nm variables and more than n equality constraints, so that the number of data entries in the constraint matrix is more than Nmn ; when N, m, n are large, the number of data entries in the standard form representation is by orders of magnitude larger than in the former, natural and compact, representation of problem’s data. Nevertheless, the standard form data clearly can be produced in a polynomial time fashion from the data of the compact representation of the problem. As a result, if we know a polynomial time algorithm \mathcal{B} for solving multicommodity flow problems represented in the standard form, we automatically know similar algorithm for these problems represented in the compact form; to build such an algorithm, we first convert in polynomial time the “compact form data” into the standard form one, and then apply to the resulting standard form problem the algorithm \mathcal{B} . The overall computation clearly is polynomial time. Note that conclusions

of this type are “automatically true” due to our somehow “loose” definition of efficiency. Were we defining an efficient algorithm as one with the complexity bounded by *linear* function of L , similar conclusions would be impossible; say, it would be unclear why efficient solvability of the problem in the standard form implies efficient solvability in the standard form, since the conversion of the data from the latter form to the former one takes non-linear, although polynomial, time.

From the viewpoint of actual computations, the simple dichotomy “polynomial – non-polynomial” is indeed loose: we would not be happy when running an algorithm with complexity of order of L^{100} . However, the loose definition of efficiency as polynomially captures perhaps not all, but at least the most crucial components of the diffuse real-life notion of efficiency. While a polynomial complexity bound *may happen* to be too big from practical viewpoint, a typical non-polynomial bound – the exponential bound $\exp\{O(1)L\}$ – definitely is too big from this viewpoint. It should be added that, as a matter of fact, the complexity bounds for the vast majority of known polynomial time algorithms are polynomials of quite moderate order, like 2 and 3, so that discussions on what is better in applications – an polynomial time algorithm with complexity L^{100} or a non-polynomial time algorithm with complexity $\exp\{0.1n\}$ – have more or less empty scope. What indeed is true, is that *after* we know that a generic problem is polynomially solvable, we can start to bother about the degrees of the related polynomials, about what is the best, from the practical viewpoint, way to organize the data, etc.

6.1.1 Models of Computations

The informal “definition” of complexity we have presented is incomplete, and the crucial yet missing element is *what is our model of computations*, what is the “computer” and its “elementary operations” we were speaking about. In our context, one could choose between two major models of computation¹, which we will refer to call the *Rational Arithmetic* and *Real Arithmetic* ones.

Real Arithmetic model of computations. You can think about this model of a computation on idealized *Real Arithmetic computer* capable to store indefinitely many real numbers and to carry out *precisely* elementary operations with these numbers – the four arithmetic operations, comparisons, and computing the values of elementary functions, like $\sqrt{}$, \exp , \sin , etc. Execution of such an operation takes unit time.

Rational Arithmetic model of computations. Here we are computing on a *Rational Arithmetic computer* capable to store indefinitely many finite binary words. We interpret these words as encoding pairs of binary-represented integers (say, “00” encodes bit 0, “11” encodes bit 1, “10” encodes sign –, and “01” separates bits and signs of the first member of the pair from those of the second member. For example, the pair of integers (3, –2) will be encoded as

$$\begin{array}{cccc} a & b & c & d \\ \underbrace{1111} & \underbrace{01} & \underbrace{10} & \underbrace{1100} \end{array}$$

where a encodes the binary representation ‘11’ of 3, b plays the role of comma, c encodes the sign –, and d encodes the binary representation ‘10’ of 2. We shall

¹In the presentation to follow, we intend to explain the essence of the matter and skip some of the technicalities.

interpret the integers encoded by a binary word as the numerator and denominator of a rational number. The operations of the Rational Arithmetic computer are the four arithmetic operations with rational numbers encoded by the operands and comparison ($>$, $=$, $<$) of the rational number encoded by the operand with 0. The time taken by an elementary operation is now not a constant, but depends on the total binary size ℓ of the operands; all what matters in the sequel is that this time is bounded from above by a fixed polynomial of ℓ .

note that our assumption on how long an operation takes corresponds to the situation when the true elementary operations, those taking unit time, are “bit-wise” – operate with operands of once for ever fixed binary length, say, with bytes. With rich enough family of these bit-wise operations, it still is possible to carry our arithmetic operations with rational numbers, but such an operation, rather than to be “built into the hardware,” is implemented as execution of a micro-program which uses the bit-wise operations only. As a result, time taken by, say, addition of two rational numbers is not a constant, it grows with the total binary size of the operands, as it is the case with computations by hand.

Needless to say, the Rational Arithmetic computer is much closer to a real-life computer than the Real Arithmetic computer is. Nevertheless, both models are meaningful idealizations of the process of actual computations; which one of the models to use, it depends on the subject area we intend to analyze. For example, the Rational Arithmetic model is *the* model used in Combinatorial Optimization which operates with fully finite entities and hardly needs even rational fractions, not speaking of reals. In contrast to this, in Continuous Optimization, especially, beyond LO, would be a complete disaster – in this area, to bother all the time on keeping the results of all computations in the field of rational numbers would be a severe obstacle to inventing and analyzing algorithms, and here a Real Arithmetic model of computations is really indispensable.

Existence of several models of computation makes the question “Whether a given generic problem \mathcal{P} is or is not polynomially solvable” somehow ill-posed. Assume that we use the Rational Arithmetic model of computations and want to know what is the solvability status of a generic problem like “Solving square nonsingular systems of linear equations,” or “Solving LO programs.” First of all, we should restrict ourselves with instances where the data vector is rational, since otherwise we cannot even load the data in our computer. Second, we should measure the size of an instance, taking into account the total binary lengths of the entries in the data vector, not only their number. Otherwise solving the linear equation as simple as $ax = b$, a and b being positive rationals, would be an intractable computational task: to solve the equation, we should compute the numerator and the denominator of the rational number b/a , and the running time of such a division on a Rational Arithmetic computer is the larger the larger is the total bit size of the four integers hidden in a, b . Thus, our equation cannot be solved in time polynomial in the *number* of data entries. To overcome this difficulty, the standard definition of the size of an instance p is the *bit length of the corresponding data*, that is, the total number of bits in the binary representation of the (rational!) entries of the data vector $\text{data}(p)$. We will refer to the resulting complexity model as to the *Combinatorial one*. Thus,

In the Combinatorial Complexity Model:

- *all instances of a generic problem have rational data vectors,*

- the size of an instance is the total bit length of its data vector, and
- computations are carried out on a Rational Arithmetic computer, so that the running time is quantified by the total number of bit-wise operations performed in course of the solution process. In particular, the running time of an arithmetic operation with rational operands is a fixed polynomial of the total binary length of the operands.

Now assume that we use the Rational Arithmetic model of computations and address “the same” generic problems “Solving square nonsingular system of linear equations” and “Solving LO programs.” Now there is no necessity to require from the data of the instances to be rational. Likewise, it is natural to define the size of an instance the number of entries (i.e., the dimension) of the corresponding data vector. We will refer to this complexity model as the *Real Arithmetic* one. Thus,

In the Real Arithmetic Complexity Model:

- instances of a generic problem may have real data vectors,
- the size of an instance is the dimension of its data vector, and
- computations are carried out on a Real Arithmetic computer, so that the running time is quantified by the total number of real arithmetic operation performed in course of the solution process. In particular, it takes unit time to perform an arithmetic operation with real operands.

For more details on Real Arithmetic Complexity Model (including, in particular, the case where we seek for *approximate* solution of a prescribed accuracy rather than for a precise solution – the situation typical for nonlinear optimization programs which cannot be solved exactly in finite number of arithmetic operations), see [1].

Note that when passing from investigating tractability of a generic problem, say, “Solving square nonsingular systems of linear equations” in the framework of CCM (Combinatorial Complexity Model) to investigating “the same” problem in the framework of RACM (Real Arithmetic Complexity Model), the task – to build a polynomial time solution algorithm – simplifies in some aspects and becomes more complicated in other aspects. Simplification comes from the fact that now we have in our disposal much more powerful computer. Complication comes from two sources. First, we extend the family of instances by allowing for real data (this is why he quotation marks in the above “the same” come from); usually, this is a minor complication. Second, and much more important, complication comes from the fact that even for instances with rational data we now want much more than before: we want the running time of our new powerful computer to be bounded by a *much smaller* quantity than before — by polynomial in the dimension of the data vector instead of polynomial in the bit size of this vector. As a result, polynomial solvability of the problem in one of the models does not say much about polynomial solvability of “the same” problem in the second model. For example, the problem of solving a square nonsingular system of linear equations is tractable — polynomially solvable — in both CCM and RACM, and the efficient solution algorithm can be chosen to be “the same,” say, Gaussian elimination. However, the meaning of the claim “Gaussian elimination allows to solve square nonsingular systems of linear equations in polynomial time” heavily depend on what is the complexity model in question. In CCM, it means that the “*bit-wise*” effort of solving a system is bounded by a polynomial in the *total bit size* of the data; from this fact we cannot

make any conclusion on how long it takes to solve a single linear equation with one variable — the answer depends on how large is the binary length of the data. The same claim in RACM means that a $n \times n$ system of linear equations can be solved in a polynomial in n time of operations of the precise Real Arithmetics (just one division in the case of 1×1 system). At the same time, the claim does not say how long it will take the system with rational data on a “real life” computer which in fact is a Rational Arithmetics one. That the latter shortcoming of the “RACM tractability” indeed is an important “real life” phenomenon, can be witnessed by everybody with even a minor experience in applications of Numerical Linear Algebra — just ask him/her about rounding errors, condition numbers, ill-posed systems and the like.

Now, what about tractability status of the main hero of our course – LO? The situation is as follows.

- The question whether LO admits a polynomial time solution algorithm in the Real Arithmetic Complexity model remains open for over 5 decades; in somehow refined form, it is included in the “short list,” compiled by the famous mathematician, Fields Laureate Stephen Smale, of the major open problems with which Mathematics enters the XXI Century. The strongest result in this direction known so far is that *when restricting the entries of the constraint matrix in a standard form LO to be integers varying in a once for ever fixed finite range, say, 0/1 or 0,1,...,10 and allowing the right hand side and the objective vectors to be real, we get a polynomially solvable in the RACM generic problem* (E. Tardos, '85 [15]).
- The question whether LO admits a polynomial time solution algorithm in the Combinatorial Complexity model of computations remained open for about three decades; it was answered positively by L.G. Khachiyan ('79, [7]); his construction, to be reproduced later in this lecture, heavily exploits the Real Arithmetic Ellipsoid Algorithm for convex optimization proposed in [8] and independently, slightly later, in [14].

6.1.2 Complexity Status of the Simplex Method

In spite of the exemplary performance exhibited by the Simplex Method in practical computations, this method is not polynomial neither in RACM, nor in CCM. Specifically, as early as in mid-1960's, Klee and Minty presented examples of simply-looking LO programs (“Klee-Minty cubes,” see [3, Section 3.7]) where the method exhibits exponential time behavior. More precisely, Klee and Minty discovered a series of concrete LO instances p_1, p_2, \dots, p_n being the design dimension of P_n , with the properties as follows:

- both the bit length and the dimension of the data vector of p_n are polynomial (just quadratic) in n ;
- the feasible set of p_n is a polytope given by $2n$ linear inequality constraints and possessing 2^n vertices, all of them nondegenerate;
- as applied to p_n , the Simplex method, started at an appropriately chosen vertex and equipped with appropriate pivoting rules compatible with method's description, arrives at the optimal vertex after 2^n iterations, that is, visiting one by one all 2^n vertices.

Since Klee and Minty presented their examples, similar “bad examples” were built for all standard pivoting rules. Strictly speaking, these examples do not prove that the Simplex Method cannot be “cured” to become polynomial. Recall that the method is not a single fully determined algorithm; it is a family of algorithms, a particular member of this family being specified by the pivoting rules in use. These rules should be compatible with certain “conceptual scheme” we

have presented when describing the method, but they are not uniquely defined by this scheme. And nobody proved yet that this scheme does not allow for implementation which does lead to a polynomial time algorithm. What could be fatal in this respect, at least in the RACM framework, is the “heavy failure to be true” of the famous *Hirsch Conjecture* as follows:

Let X be a polyhedral set given by m linear inequality constraints on n variables and not containing lines. Every two vertices of X can be linked to each other by a path of at most $m - n$ consecutive edges (one-dimensional faces such that the end vertex of an edge from the path is the start vertex in the next edge from it).

If this long-standing conjecture is in fact “severely wrong,” and the maximin number

$$N(m, n) = \max_{X, v, v'} \min_{\text{paths}} \{\# \text{ of path edges}\}$$

of edges in an edge path (the maximum is taken over all “line-free” polyhedra X given by m linear inequalities on n variables and over all pairs of vertices v, v' of X , the minimum is taken over all edge paths on X linking v and v') grows with m, n faster than every polynomial of $m + n$, then the Simplex method cannot be cured to become a polynomial time one. Indeed, given the polyhedral set X long with its vertices v, v' corresponding to the above maximin, we can make v' the unique optimal solution to $\min_X c^T x$ (Proposition 3.1.3), and v – the vertex the Simplex method starts with when solving this program. Whatever be the pivoting rules, the number of vertices visited by the Simplex method when solving the program clearly will be bounded from below by $N(m, n)$, and the latter quantity, if Hirsch was severely mistaken in his conjecture, grown with m, n in a super-polynomial fashion.

The current status of the Hirsch Conjecture is as follows. For polytopes (i.e., nonempty and bounded polyhedral sets) its validity remains open. For unbounded polytopes, it is disproved by Klee and Walkup '67 who demonstrated that

$$H(m, n) \geq m - n + \text{floor}(n/5);$$

this lower bound on $H(m, n)$, however, does not lead to any fatal consequences regarding potential polynomiality of the Simplex method. As far as an upper bound on $H(m, n)$ is concerned, the best known bound, due to Kalai and Kleitman '93, is

$$N(m, n) \leq n^{\log_2 m};$$

while being sub-exponential, it is not polynomial. The bottom line is that to make the Simplex method polynomial is not easier than to prove a somehow relaxed (a polynomial in m, n instead of $m - n$) version of the long standing Hirsch Conjecture.

6.1.3 *Classes P and NP

Here we briefly explain the notions of complexity classes P and NP are of paramount importance in CCM; while we do not directly use them in what follows, it would be unwise to omit this topic. In what follows, we deal with the Combinatorial Complexity model only.

Consider a generic problem \mathcal{P} with rational data, and let it be a *decision problem*, meaning that a candidate solution to an instance is just the answer “yes, the instance possesses certain property P ,” or “no, the instance does not possess the property P ,” the property in question is part of the description of the generic problem \mathcal{P} . Examples are:

- [Shortest path] “Given a graph with arcs assigned nonnegative integral weights, two nodes in the graph, and an integer M , check whether there exists a path of length² $\leq M$ linking these

²defined as the sum of lengths of edges constituting the path

two nodes”

- [Traveling salesman] “Given a graph with arcs assigned nonnegative integral weights and an integer M , check whether there exists a tour (cyclic path which visits every node exactly once) of length $\leq M$ ”
- [Stones] “Given positive integral weights a_1, \dots, a_n of n stones, check whether the stones can be split into two groups of equal total weights”
- [Decision version of LO] “Given LO program with rational data, check its feasibility”

A decision problem is in class NP, if the positive answer is “easy to certify.” Specifically, there exists a predicate $\mathcal{A}(x, y)$ (a function of two finite binary words x, y taking values 0 and 1) and a polynomial $\pi(\ell)$ such that

1. The predicate is polynomially computable — there exists a code for the Rational Arithmetic computer which, given on input a pair of binary words x, y , computes $\mathcal{A}(x, y)$ in the a polynomial in $\ell(x) + \ell(y)$ number of bit-wise operations; here and in what follows $\ell(\cdot)$ is the bit length of a binary word;
2. For every x , if there exists y such that $\mathcal{A}(x, y) = 1$, then there exists a “not too long” y' with the same property $\mathcal{A}(x, y') = 1$, specifically, such that $\ell(y) \leq \pi(\ell(x))$;
3. An instance p of \mathcal{P} possesses property P iff the data $\text{data}(p)$ of the instance can be augmented by certain y in such a way that $\mathcal{A}(\text{data}(p), y) = 1$.

We assume that the predicate \mathcal{A} , the polynomial time algorithm computing this predicate, and polynomial π are part of the description of the generic problem \mathcal{P} .

Comments: A. \mathcal{P} is a generic program with rational data, so that $\text{data}(p)$ is a finite sequence of integers; we always can encode such a sequence by a finite binary word (cf. encoding of $(3, -2)$ above). After the encoding scheme is fixed, we can think of $\text{data}(p)$ as of a binary word, and 3) above makes sense.

B. The structure of the above definitions is well known to us. They say that presence of the property P in an instance p is easy to certify: a certificate is a binary word y which, taken along with the data of p , satisfies the condition $\mathcal{A}(\text{data}(p), y) = 1$, and this certification scheme is complete. Moreover, given $\text{data}(p)$ and candidate certificate y , it is easy to verify whether y is a valid certificate, since $\mathcal{A}(\cdot, \cdot)$ is polynomially computable. Finally, given p , we can point out a *finite* set $C(p)$ of candidate certificates such that if p possesses property P , then the corresponding certificate can be found already in $C(p)$. Indeed, it suffices to take, as $C(p)$, the set of all binary words y with $\ell(y) \leq \pi(\ell(x))$, see 2).

It is easily seen that all decision problems we have listed above as examples (except, perhaps, the decision version of LO) are in the class NP. E.g., in the Shortest path problem, a candidate certificate y encodes a loop-free path in a graph³ In order to compute $\mathcal{A}(\text{data}(p), y)$, we first check that whether y is a loop-free path in the graph represented by p , and then compute the length of this path and compare it with the threshold M (which is part of the data of p); you can easily verify that this construction meets all the requirements in 1) – 3).

The only example in our list for which its membership in NP is not completely evident is the decision version of LO with rational data. Of course, we understand how to certify the feasibility of an LO program — just by pointing out its feasible solution. The question, however,

³that is, a finite sequence of distinct from each other positive integers, like $(1, 17, 2)$, meaning that the consecutive arcs in the path are $(1, 17)$ and $(17, 2)$; we assume that the nodes in a graph are identify by their serial numbers.

is why such a certificate, if it exists, can be chosen to be rational with “not too long” binary representation. What we need here is the following statement:

(!) *If a system of linear inequalities with rational data of total bit length L is feasible, then it admits a rational solution with total bit length of the entries bounded by a fixed polynomial of L .*

The validity of this statement can be easily derived from what we already know, specifically, from algebraic characterization of extreme points of polyhedral sets, see Step 1 in the proof of Theorem 6.3.1 below. With (!) in our disposal, the fact that the decision version of LO with rational data is in NP.

The class P is, by definition, a subclass of NP comprised of all *polynomially solvable* problems in NP.

A decision problem $\mathcal{P} \in P$ clearly admits a finite solution algorithm. Indeed, given an instance p of \mathcal{P} , we can look, one by one, at all candidate certificates y with $\ell(y) \leq \pi(L)$, where $L = \ell(\text{data}(p))$ is the bit size of p . Each time we check whether y is a valid certificate (this reduces to computing $\mathcal{A}(\text{data}(p), y)$, which is easy). When a valid certificate is found, we terminate and claim that p possesses property P , and if no valid certificate is found when scanning all $2^{\pi(L)}$ of our candidates, we can safely claim that p does not possess the property. While being finite, this algorithm is *not* polynomial, since the number $2^{\pi(L)}$ of candidates we should scan is not bounded by a polynomial of the bit size L of p . Thus, while every problem belonging to NP admits a finite solution algorithm, it is unclear whether it is tractable — belongs to P.

The question whether $P = NP$ is *the major open question* in Complexity Theory and in Theoretical Computer Science; it also belongs to Smale’s list of major mathematical challenges. The extreme importance of this question stems from the fact that *essentially every problem in Combinatorics, Boolean and Integer Programming, etc., can be reduced to solving a “small series” of instances of an appropriate decision problem from NP*, specifically, in such a way that a polynomial time solution algorithm for the decision problem can be straightforwardly converted into a polynomial time solution algorithm for the original problem.

E.g., the optimization version of the Travelling salesman problem “given a graph with arcs assigned nonnegative integral lengths, find the shortest tour” can be reduced to small series of instances of the decision version of the same problem, where instead of minimizing the length of a tour one should check whether there exists a tour of the length not exceeding a given bound (think what this reduction is). Similarly, *solving* LO programs with rational data reduces to a small series of decision problems “check whether a given system of linear inequalities with rational data is feasible,” see Step 2 and Step 3 in the proof of Theorem 6.3.1 below.

Thus, if NP were equal to P, our life would become a paradise — there would be no difficult, at least from the theoretical viewpoint, computational problems at all! Unfortunately, even after over 4 decades of intensive studies, we do not know whether $P=NP$. The common belief is that this is not the case, and the reason stems from the fundamental discovery of *NP-complete* problems.

Polynomial reducibility and NP-completeness. Consider two generic decision problems with rational data, \mathcal{P} and \mathcal{P}' . We say that \mathcal{P}' can be polynomially reduced to \mathcal{P} , if the data $\text{data}(p')$ of every instance $p' \in \mathcal{P}'$ can be converted in *polynomial time* into the data of an

instance $p[p']$ of \mathcal{P} such that the answers in p' and in $p[p']$ are the same – or both are “yes”, or both are “no.” In this situation, tractability of \mathcal{P} automatically implies tractability of \mathcal{P}' ; indeed, to solve an instance p' of \mathcal{P}' , we first convert its data in polynomial time in the data of $p[p']$ and then solve $p[p']$ by a polynomial time solution algorithm for \mathcal{P} (\mathcal{P} is tractable!); the answer we get is the desired answer for p' , and the overall computation is polynomial⁴. In particular, if \mathcal{P} and \mathcal{P}' are polynomially reducible to each other, their tractability status is the same.

Now, a problem \mathcal{P} from the class NP is called *NP-complete*, if every problem from NP is polynomially reducible to \mathcal{P} . Thus, all NP-complete problems have the same tractability status; moreover, if one of them is polynomially solvable, then so are *all* problems from NP, and thus $P=NP$.

The major discovery in Complexity Theory we have mentioned is that *NP-complete problems do exist*. Moreover, it turned out that nearly all difficult problems in Combinatorics — those for which no polynomial time algorithms were known — are NP-complete — “as difficult as a problem from NP can be.” For example, in our list of examples, the Shortest path problem is polynomially solvable, while the Travelling salesman and the Stones problems, are NP-complete. Eventually, nearly all interesting problems from NP fell in one of just two groups: NP-complete and polynomially solvable. There is just a handful of exceptions – problems from NP which still are not known neither to be NP-complete, nor to be polynomially solvable.

Now we can explain why the common expectation is that $NP \neq P$ (or, which is the same, that NP-complete problems are intractable), so that in our current practice, the verdict “problem \mathcal{P} is NP-complete” is interpreted as lack of hope to solve the problem efficiently. As we have already mentioned, the vast majority of NP-problems are known to be NP-complete and thus, in a sense, form a single problem. This “single problem” in various forms arises in, and often is vitally important for, a huge spectrum of applications. Due to their vital importance, these problems over decades were subject of intensive research of many thousands of excellent scholars. Since all these scholars were in fact solving the same problem, it is highly unlikely that all of them overlooked the possibility to solve this problem efficiently.

6.2 The Ellipsoid Algorithm

In this section, important by its own right, we make a crucial step towards demonstrating that LO is polynomially solvable in the Combinatorial Complexity model. Surprisingly, this step seems to have nothing to do with LO; the story to be told is about a particular algorithm for solving black-box-oriented convex problems.

6.2.1 Problem and Assumptions

The Ellipsoid Algorithm (EA) is a “universal” method for solving convex optimization problems in the form

$$\text{Opt} = \min_{x \in X} f(x) \tag{6.2.1}$$

where $X \subset \mathbf{R}^n$ is a *solid* – a closed convex set with a nonempty interior, and $f : \mathbf{R}^n \rightarrow \mathbf{R}$ is a convex function. To stick to the policy “minimum of Calculus” we follow in our course, we

⁴To see this, note that the bit size of $p[p']$ is bounded by a polynomial of the bit size of p' ; indeed, in the CCM, the bit size of the output of a polynomial time computation is bounded by a polynomial of the bit size of the input (it takes unit time just to write down a single bit in the output).

assume from now on that $f(x)$ is the maximum of finitely many differentiable convex functions f_1, \dots, f_M :

$$f(x) = \max_{1 \leq i \leq M} f_i(x), \quad (6.2.2)$$

while X is cut off \mathbf{R}^n by finitely many constraints $g_i(x) \leq 0$, where g_i are differentiable convex functions:

$$X = \{x \in \mathbf{R}^n : g_i(x) \leq 0, 1 \leq i \leq N\}. \quad (6.2.3)$$

Black box representation of (6.2.1). In what follows, we assume that the descriptions of f as the maximum of finitely many differentiable convex functions and of X as the set given by finitely many convex inequality constraints with differentiable right hand sides “exist in the nature,” but not necessarily are accessible for a solution algorithm. For the latter, the problem is given by two *oracles*, or *black boxes* – routines the algorithm can call to get their outputs. The oracles are as follows:

- *Separation Oracle* which, given on input a query point $x \in \mathbf{R}^n$, “says” on the output whether or not $x \in X$, and if it is not the case, returns a *separator* — a nonzero vector $e \in \mathbf{R}^n$ such that

$$e^T(x - x') > 0 \quad \forall x' \in X; \quad (6.2.4)$$

Note that $e \neq 0$, since X is nonempty.

- *First Order Oracle* which, given on input a query point $x \in \mathbf{R}^n$, returns the value $f(x)$ and a *subgradient* $f'(x)$ of f at x .

A *subgradient* of a convex function $h : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{+\infty\}$ at a point $x \in \text{Dom } h$ is, by definition, a vector $e \in \mathbf{R}^n$ such that $h(y) \geq h(x) + e^T(y - x)$ for all y . If a convex function h is differentiable at a point x from its domain, one can take, as a subgradient of h at x , the gradient $\nabla h(x)$ of h at x ; the easy to prove fact is that $\nabla h(x)$ indeed is a subgradient:

$$h(y) \geq h(x) + [\nabla h(x)]^T(y - x) \quad \forall y$$

is called *gradient inequality for convex functions*; it expresses the quite intuitive fact that the graph of a convex function is above its tangent hyperplane. In fact, subgradients do exist at every *interior* point of the domain of a convex function. A subgradient of a given function at a given point not necessary is unique (think what are the subgradients of the function $h(x) = |x|$ at $x = 0$).

One of the ways to build a Separation and a First Order oracles is as follows:

- *Separation oracle*: given on input a point x , we compute one by one the quantities $g_i(x)$ and check whether they are nonnegative. If it is the case for all i , then $x \in X$, and we report this outcome to the algorithm. If $g_{i_*}(x) > 0$ for certain i_* , we report to the algorithm that $x \notin X$ and return, as a separator, the vector $e = \nabla g_{i_*}(x)$. This indeed is a separator, since by gradient inequality

$$g_{i_*}(y) \geq g_{i_*}(x) + e^T(y - x),$$

meaning that if $y \in X$, so that $g_{i_*}(y) \leq 0$, we have $e^T(x - y) \geq g_{i_*}(x) - g_{i_*}(y) \geq g_{i_*}(x) > 0$.

- *First Order Oracle:* given on input a point x , we compute one by one all the quantities $f_i(x)$ and pick the largest of them, let it be $f_{i_*}(x)$; thus, $f(x) = \max_i f_i(x) = f_{i_*}(x)$. We return to the algorithm the real $f_{i_*}(x)$ as the value, and the vector $\nabla f_{i_*}(x)$ – as a subgradient of f at x . To justify correctness of this procedure, note that by the gradient inequality as applied to the convex and differentiable function $f_{i_*}(\cdot)$, we have $f_{i_*}(y) \geq f_{i_*}(x) + [\nabla f_{i_*}(x)]^T(y - x)$ for all y ; the left hand side in this inequality is $\leq f(y)$, and the right hand side is equal to $f(x) + [\nabla f_{i_*}(x)]^T(y - x)$, so that $f(y) \geq f(x) + [\nabla f_{i_*}(x)]^T(y - x)$ for all y , as claimed.

A priori information on (6.2.1) is comprised of two positive reals $R \geq r$ such that X is contained in the Euclidean ball $B^R = \{x \in \mathbf{R}^n : \|x\|_2 \leq R\}$, and there exists \bar{x} such that the Euclidean ball $\{x : \|x - \bar{x}\|_2 \leq r\}$ is contained in X . Recall that X was assumed to be bounded and with a nonempty interior, so that the required R and r “exist in the nature.” We assume that these “existing in the nature” quantities are known to the solution algorithm (note: we do *not* assume that the center \bar{x} of the second ball is known to the algorithm). It should be mentioned that the a priori knowledge of R is crucial, while the knowledge of r does not affect the iterations and is used in the termination criterion only. In fact with appropriate modification of the method (see [9]), we can get rid of the necessity to know r .

In addition, we assume that we are given an a priori bound $V < \infty$ on the *variation* $X(f) := \max_x f - \min_X f$ of the objective on the feasible set.

Here is a simple way to build V . Calling the First Order Oracle at $x = 0$, we get $f(0)$ and $f'(0)$, thus getting an affine lower bound $\ell(x) = f(0) + [f'(0)]^T x$ on $\ell(x)$. Minimizing this bound over the ball B^R which contains X , we get a lower bound $\text{Opt} = f(0) - R\|f'(0)\|_2$ on Opt . Further, we build $n + 1$ points x_0, \dots, x_n in such a way that their convex hull Δ contains the ball B^R and thus contains X . Calling the First Order Oracle at these $n + 1$ points, we build the quantity $F = \max_{0 \leq i \leq n} f(x_i)$.

By Jensen’s inequality, $f(x) \leq F$ for all $x \in \Delta$ and thus for all $x \in X$ (since $X \subset B_R \subset \Delta$). It follows that the quantity $F - \text{Opt} \geq \max_{x \in X} f(x) - \text{Opt}$ can be taken as V .

The goal. Our goal is, given access to the oracles, the outlined a priori information and an $\epsilon > 0$, to find an ϵ -solution to (6.2.1), that is, a feasible solution x_ϵ such that $f(x_\epsilon) \leq \text{Opt} + \epsilon$.

6.2.2 The Ellipsoid Algorithm

After we have specified our goal – solving (6.2.1) within a given accuracy $\epsilon > 0$, our oracle-based “computational environment, and our a priori information, we are ready to represent the Ellipsoid Algorithm. We start with recalling what an ellipsoid is.

Ellipsoids in \mathbf{R}^n . An ellipsoid E in \mathbf{R}^n is, by definition, a set representable as the image of the unit Euclidean ball under an invertible affine transformation $x \mapsto Bx + c$:

$$E = \{x = Bu + c : u^T u \leq 1\} \quad [B : n \times n \text{ nonsingular}]$$

Recall that under an invertible affine transformation $x \mapsto Bx + c$ the n -dimensional volumes of bodies in \mathbf{R}^n are multiplied by $|\text{Det}(B)|$. Taking, as the unit of n -dimensional volume, the volume of the unit n -dimensional ball, we therefore have

$$\text{Vol}(E) = |\text{Det}(B)|.$$

Figure 6.1: Building a “small” ellipsoid containing a half-ellipsoid.

We need the following

Lemma 6.2.1 *Given an ellipsoid $E = \{Bu + c : u^T u \leq 1\}$ in \mathbf{R}^n , $n > 1$, and a nonzero e , let $\hat{E} = \{x \in E : e^T x \leq e^T c\}$ be the half-ellipsoid cut off E by the linear inequality $e^T x \leq e^T c$ in variable x (geometrically: we take the hyperplane $\{x : e^T x = e^T c\}$ passing through the center c of the ellipsoid E . This hyperplane splits E in two parts, and \hat{E} is one of these parts) Then \hat{E} is contained in an explicitly given ellipsoid E^+ with the volume strictly less of the one of E , specifically, in the ellipsoid*

$$E^+ = \{x = B_+ u + c_+ : u^T u \leq 1\}, \text{ where} \quad (6.2.5)$$

$$B_+ = B \left(\frac{n}{\sqrt{n^2-1}} (I_n - pp^T) + \frac{n}{n+1} pp^T \right) = \frac{n}{\sqrt{n^2-1}} B + \left(\frac{n}{n+1} - \frac{n}{\sqrt{n^2-1}} \right) (Bp)p^T,$$

$$c_+ = c - \frac{1}{n+1} Bp, \quad p = \frac{B^T e}{\sqrt{e^T B B^T e}}$$

The volume of the ellipsoid E^+ satisfies

$$\text{Vol}(E^+) = \left(\frac{n}{\sqrt{n^2-1}} \right)^{n-1} \frac{n}{n+1} \text{Vol}(E) \leq \exp\{-1/(2(n+1))\} \text{Vol}(E). \quad (6.2.6)$$

Proof. We only sketch the proof, leaving completely straightforward, although somehow tedious, computations to a reader. The key observation is that we can reduce our statement to the one where E is the unit Euclidean ball. Indeed, E is the image of the unit ball $U = \{u : \|u\|_2 \leq 1\}$ under the mapping $u \mapsto Bu + c$; \hat{E} is the image, under the same mapping, of the half-ball $\hat{U} = \{u \in U : f^T u \leq 0\}$, where $f = B^T e$. Choosing appropriately the coordinates in the u -space, we can assume that $\hat{U} = \{u \in U : u_n \leq 0\}$. Now, invertible affine mappings preserve ratio of volumes and map ellipsoids onto ellipsoids. It follows that in order to cover \hat{E} by a “small” ellipsoid E^+ , it suffices to cover the half-ball \hat{U} by a “small” ellipsoid U^+ and to take, as E^+ , the image of U^+ under the mapping $u \mapsto Bu + c$ (see figure 6.1). Let us take, as U^+ , the smallest volume ellipsoid containing \hat{U} . The latter is easy to specify: by symmetry, its center should belong to the n th coordinate axis in the u -space, and U^+ should be the result of rotating a 2D ellipsis shown on figure 6.1 around this axis. “By minimality,” this ellipsis should look as shown on the picture: its boundary should pass through the $[0; -1]$ and the “equatorial points” $[\pm 1; 0]$ of the unit circle; which specifies the ellipsis up to the “height” h of its center. The half-axis of the ellipsis are easy-to-compute functions $p(h)$ and $q(h)$ of h ; the ellipsoid U^+ has

$n - 1$ of its half-axes equal to the largest of the half-axes of the ellipsis, let i be $P(h)$, and one half-axis equal to the smaller half-axis $q(h)$ of the ellipsis. Since the volume of an ellipsoid is proportional to the product of its half-axes, and we want to minimize the volume, we need to minimize the univariate function $p^{n-1}(h)q(h)$. This problem has a closed form solution, and this solution underlies the formulas in (6.2.5). \square

The Ellipsoid Algorithm. Now we are ready to present the EM. The idea of the method is very simple and looks as a natural multidimensional extension of the usual Bisection. Specifically, we build a sequence of ellipsoids of decreasing volume which “localize” the optimal set of the problem; it turns out that when the latter is localized is an ellipsoid of a small enough volume, we automatically have in our disposal a good approximate solution. In what follows, the italicized text constitutes the description of the algorithm; the paragraph printed in Roman contain explanations, comments, etc. We describe the method in geometric terms; their algebraic (and thus algorithmic) “translation” is readily given by formulas in (6.2.5).

- Initialization: We specify E_0 as the ball $B^R = \{x \in \mathbf{R}^n : \|x\|_2 \leq R\}$.
Note that this ball contains X and thus contains the optimal set of (6.2.1).
- Step $t = 1, 2, \dots$: At the beginning of step t , we have in our disposal the current localizer – an ellipsoid E_{t-1} ; let x_t be the center of this ellipsoid. At step t we act as follows.

1. We call the Separation Oracle, x_t being the input. If the oracle reports that $x_t \in X$, we call step t productive and go to rule 2, otherwise we call step t non-productive, denote by e_t the separator reported by the oracle and go to rule 3.
2. We call the First Order Oracle, x_t being the input, and set $e_t = f'(x_t)$. If $e_t = 0$, we terminate and claim that x_t is an optimal solution to (6.2.1), otherwise we go to rule 3.

Note that we arrive at rule 2 only when $x_t \in \text{int } X$. If $e_t := f'(x_t) = 0$, then by the definition of a subgradient, $f(y) \geq f(x_t) + [f'(x_t)]^T(y - x_t) = f(x_t)$ for all y , meaning that x_t is a global minimizer of f ; since we are in the situation when x_t is feasible for (6.2.1), the claim we make upon termination according to rule 3 is correct.

3. We set $\hat{E}_t = \{x \in E_{t-1} : e_t^T x \leq e_t^T x_t\}$, build the ellipsoid E_t which covers \hat{E}_t according to the recipe from Lemma 6.2.1 and go to rule 5.

Since a separator always is nonzero and in view of the termination rule in 2, we arrive at rule 3 with $e_t \neq 0$, which makes \hat{E}_t a half-ellipsoid and thus makes Lemma 6.2.1 applicable. Besides this, we note – and this explains the idea of the construction – that \hat{E}_t (and thus $E_t \supset \hat{E}_t$) inherits the property of E_{t-1} to localize the optimal set of (6.2.1). Indeed, if step t is non-productive, then e_t separates x_t and X , whence $e_t^T(x_t - x) > 0$ for all $x \in X$. Looking at the formula defining \hat{E}_t , we see that what we cut off E_{t-1} when passing from the ellipsoid E_{t-1} to its half \hat{E}_t is outside of X , i.e., not only optimal, but even feasible solutions to the problem which “sit” in E_{t-1} sit also in \hat{E}_t . Now let t be a productive step. In this case x_t is a feasible solution to the problem, and $e_t = f'(x_t)$. by the definition of a subgradient, we have $f(x) \geq f(x_t) + [f'(x_t)]^T(x - x_t)$, meaning that for all points $x \in E_{t-1} \setminus \hat{E}_t$ it holds $f(x) > f(x_t)$. Since x_t is feasible, it follows that when passing from E_{t-1} to \hat{E}_t , no optimal solutions are thrown away.

4. We check whether the volume of the ellipsoid E_t satisfies the inequality

$$\text{Vol}^{1/n}(E_t) < \frac{r\epsilon}{V}. \quad (6.2.7)$$

If it is the case, we terminate and output, as the approximate solution \hat{x} generated by the method, the best – with the smallest value of f – of the points x_τ corresponding to productive steps $\tau \leq t$. Otherwise, we pass to step $t + 1$.

We shall check in a short while that the termination rule 4 is well defined, meaning that upon termination according to this rule, the set of productive steps performed so far is nonempty, so that the approximate solution is well defined.

Correctness and performance guarantees. We are about to prove the following

Theorem 6.2.1 *Under the assumptions from section 6.2.1, given a required accuracy ϵ , $0 < \epsilon < V$, the Ellipsoid method terminates after finitely many steps and returns a feasible approximate solution to x_ϵ to (6.2.1) such that $f(x_\epsilon) \leq \text{Opt} + \epsilon$. The number $N(\epsilon)$ of steps before termination can be upper bounded as*

$$N(\epsilon) \leq O(1)n^2 \ln \left(2 + \frac{V}{\epsilon} \cdot \frac{R}{r} \right), \quad (6.2.8)$$

where $O(1)$ is an absolute constant, and V is an a priori upper bound on $\max_{x \in X} f(x) - \text{Opt}$, R is an a priori upper bound on the size of X (specifically, such that X is contained in $E_0 = \{x : \|x\|_2 \leq R\}$), and $r > 0$ is an a priori lower bound on the largest of radii of Euclidean balls contained in X .

A step of the method requires at most two calls to the Separation and the First Order oracles, augmented by $O(1)n^2$ arithmetic operations to process the answers of the oracles.

Proof. The last statement, describing the effort per step, is readily given by the description of the method and formulas (6.2.5) explaining how to convert the description of E_{t-1} into the description of E_t .

To prove the upper bound on the number of steps, note that in view of (6.2.6) we have $\text{Vol}(E_t) \leq \text{Vol}(E_0) \exp\{-\frac{t}{2(n+1)}\} = R^n \exp\{-\frac{t}{2(n+1)}\}$; since at every step except for the last one, the inequality opposite to (6.2.7) holds true, (6.2.8) follows.

It remains to verify that the algorithm does produce a result, and this result is a feasible ϵ -solution to the problem. There is nothing to prove if algorithm terminates according to rule 2 (indeed, it was explained in the comment to this proof that in this case the algorithm returns an optimal solution to the problem). Thus, assume that the algorithm does not terminate according to rule 2. Let x_* be an optimal solution to (6.2.1) and let $\theta = \epsilon/V$, so that $0 < \theta < 1$. Let us set

$$X_* = (1 - \theta)x_* + \theta X,$$

so that $\text{Vol}(X_*) = \theta^n \text{Vol}(X) \geq \theta^n r^n$. Let T be the termination step. We claim that E_T cannot contain X_* . Indeed, otherwise we would have $\text{Vol}(X_*) \leq \text{Vol}(E_T)$, whence $\text{Vol}(E_T) \geq \theta^n r^n = (\epsilon/V)^n r^n$. But this contradicts the termination criterion (6.2.7) in rule 4, and this criterion should be satisfied at step T , since this is the termination step.

We have proved that $X_* \setminus E_T \neq \emptyset$, so that there exists $y \in X_*$ such that $y \notin E_T$. By construction of X_* we have $y = (1 - \theta)x_* + \theta z$ for some $z \in X$, whence, in particular, $y \in X$ (since X is convex). Thus, $y \in X \subset E_0$ and $y \notin E_T$; thus, there is a step $\tau \leq t$ such that $y \in E_{\tau-1}$ and $y \notin E_\tau$. since $E_\tau \supset \hat{E}_\tau$, we conclude that $y \notin \hat{E}_\tau$. The bottom line is that at

certain step $\tau \leq T$ the point y satisfies the inequality $e_\tau^T y > e_\tau^T x_\tau$ (see the relation between $E_{\tau-1}$ and \hat{E}_t). Now, τ is a productive step, since otherwise e_τ would separate x_τ and X , meaning that $e_\tau^T x' < e_\tau^T x_\tau$ for all $x' \in X$, and in particular for $x' = y$ (we have seen that $y \in X$). Since τ is a productive step, the result \hat{x} of the algorithm is well defined, is feasible and satisfies the relation $f(\hat{x}) \leq f(x_\tau)$, see rule 4. It follows that

$$f(\hat{x}) \leq f(x_\tau) = f((1 - \theta)x_* + \theta z) \leq (1 - \theta)f(x_*) + \theta f(z) = f(x_*) + \theta(f(z) - f(x_*)),$$

where the second inequality is due to the fact that f is convex. It remains to note that the last quantity in the chain, due to the origin of V , is $\leq f(x_*) + \theta V = f(x_*) + \epsilon$. Thus, $f(\hat{x}) \leq \text{Opt} + \epsilon$. \square

Discussion. Let us explain why the statement of Theorem 6.2.1 is truly remarkable. The point is that in the complexity bound (6.2.8) the desired accuracy ϵ and the “data-dependent” parameters V, R, r are under the logarithm; the only parameter which is not under the logarithm is the *structural* parameter n . As a result, the iteration count $N(\epsilon)$ is “nearly independent” of ϵ, V, R, r and is polynomial – just quadratic – in n . Another good news is that while we cannot say exactly how large is the computational effort per step – it depends on “what goes on inside the Separation and First Order oracles,” we do know that *modulo the computations carried out by the oracles*, the Real Arithmetic complexity of a step is quite moderate – just $O(1)n^2$. Now assume that we use the Real Arithmetic Complexity model and want to solve a generic problem \mathcal{P} with instances of the form (6.2.1) – (6.2.3). If the functions f_i and g_i associated with an instance $p \in \mathcal{P}$ of the problem are *efficiently computable* (that is, given x and the data of an instance $p \in \mathcal{P}$, we can compute the taken at x values and the gradients of all f_i and g_i in polynomial in $\text{Size}(p) = \dim \text{data}(p)$ time), then the RACM-complexity of an iteration becomes polynomial in the size of the instance. Under mild additional assumptions on \mathcal{P} (see [1, Chapter 5]), polynomially of the per-iteration effort combines with low – just logarithmic – dependence of the iteration count $N(\epsilon)$ on ϵ to yield an *algorithm which, given on input the data of an instance $p \in \mathcal{P}$ and a desired accuracy $\epsilon > 0$, finds an ϵ -solution to p in a number of Real Arithmetic operations which is polynomial in the size of the instance and in the number $\ln(1/\epsilon)$ of accuracy digits we want to get.*⁵

Historically, the Ellipsoid Algorithm was the first universal method for solving black-box-represented convex problems with iteration count polynomial in problem’s dimension n and in the number $\ln(1/\epsilon)$ of accuracy digits we want to get, and with polynomial in n “computational overhead” (computational effort modulo the one of the oracles) per iteration⁶. As we shall see in a while, these properties of the EA are instrumental when demonstrating CCM-tractability of LO with rational data.

⁵In the RACM framework, algorithms of this type usually are called polynomial time ones. The reason is that aside of a handful of special cases, generic computational problems with real data do not admit finite (i.e., with a finite on every instance running time) algorithms capable to solve the instances *exactly*. By this reason, it makes sense to relax the notion of efficient – polynomial time – algorithm, replacing the ability to solve instances *exactly* in RACM-time polynomial in their sizes, with the ability to solve instances within a prescribed accuracy $\epsilon > 0$ in RACM-time polynomial in the size of an instance *and* $\ln(1/\epsilon)$. Of course, such a relaxation requires to decide in advance how we quantify the accuracy of candidate solutions, see [1, Chapter 5] for details.

⁶Now we know a handful of other methods with similar properties

6.3 Polynomial Solvability of LO with Rational Data

Our goal here is to prove the following fundamental fact:

Theorem 6.3.1 L.G. Khachiyan] *In Combinatorial Complexity model, Linear Optimization with rational data is polynomially solvable.*

Proof. In what follows, “polynomial time” always means “polynomial time in the Combinatorial Complexity model of computations.”

Step I: Checking feasibility of a system of linear inequalities. We start — and this is the essence of the proof — with demonstrating polynomial solvability of the following *feasibility problem*:

Given a system of linear inequalities $Ax \leq b$ with rational data, check whether the system is or is not feasible.

Note that we do not want to *certify* the answer: all we want is the answer itself.

Multiplying the constraints by appropriate positive integers, we can make all the entries in A and in b integral; it is easy to verify that this transformation can be carried out in polynomial time. Further, we can get rid of the kernel of A by eliminating, one by one, columns of A which are linear combinations of the remaining columns. This is a simple Linear Algebra routine which takes polynomial time. Thus, we lose nothing by assuming that the original system of constraints is with integer data, and A has trivial kernel. In the sequel, we denote by m and n the sizes (numbers of rows and columns) of A , and by L — the bit size of $[A, b]$.

Our plan of attack is as follows: We observe that feasibility of the system $Ax \leq b$ is equivalent to the fact that the simple piecewise linear function

$$f(x) = \max_{1 \leq i \leq m} [a_i^T x - b_i].$$

Note that the system $Ax \leq b$ is feasible iff f is not everywhere positive. We intend to prove two facts:

- A.** If f is not everywhere positive, that is, attains nonpositive values, it attains nonpositive values already in the box $X = \{x : \|x\|_\infty := \max_i |x_i| \leq M = 2^{O(1)L}\}$.

An immediate consequence is that *the system $Ax \leq b$ is feasible iff the optimal value in the convex optimization problem*

$$\text{Opt} = \min_x \left\{ f(x) = \max_{1 \leq i \leq m} [a_i^T x - b_i] : \|x\|_\infty \leq M = 2^{O(1)L} \right\} \quad (6.3.1)$$

is ≤ 0 .

- B.** If the optimal value in (6.3.1), it is not too close to 0:

$$\text{Opt} > 0 \Rightarrow \text{Opt} \geq \alpha := 2^{-O(1)L}. \quad (6.3.2)$$

Taking **A** and **B** for granted, a polynomial time algorithm for solving the Feasibility problem can be built as follows: we apply to (6.3.1) the Ellipsoid method, the target accuracy being $\epsilon = \alpha/3$. As a result, we will get an approximate solution x_ϵ to the problem such that $\text{Opt} \leq$

$f(x_\epsilon) \leq \text{Opt} + \epsilon = \text{Opt} + \alpha/3$. Therefore, computing $f(x_\epsilon)$, we get an approximation of Opt accurate within the error $\alpha/3$. Since, by **B**, either $\text{Opt} \leq 0$, or $\text{Opt} \geq \alpha$, this approximation allows us to say *exactly* which one of the options takes place: if $f(x_\epsilon) \leq \alpha/2$, then $\text{Opt} \leq 0$, and thus, by **A**, the answer in the Feasibility problem is “yes”, otherwise $\text{Opt} \geq \alpha$, and the answer in the problem, by the same **A**, is “no”.

It remains to understand how to apply the Ellipsoid Algorithm to (6.3.1). First what we need are a Separation oracle for the box $\{x : \|x\|_\infty \leq M\}$ and a First Order oracle for f ; these oracles can be built according to the recipe described in section 6.2.1. Note that a single call to an oracle requires no more than mn operations. Next what we need is the a priori information R, r, V . This information is immediate: we can take $R = M\sqrt{n} = \sqrt{n}2^{O(1)L}$, $r=M$ and $V = 2M(n+1)2^L$, where the latter bound comes from the evident observation that the magnitudes of all entries in A and b do not exceed 2^L , so that $|a_i^T x - b_i|$ is bounded from above by $2^L(n+1)$ provided $\|x\|_\infty \leq L$.

Invoking the complexity bound for the Ellipsoid method and taking into account that $M = 2^{O(1)L}$ the total number of iterations before termination is polynomial in n and L (since all exponents $2^{O(1)L}$ will appear under the logarithm), and thus is polynomial in L due to $mn \leq L$ (indeed, we have more than $m(n+1)$ entries in the data $[A, b]$, and it takes at least one bit to represent a single entry. Since the number of arithmetic operations at a step of the method (including those spent by the oracles) is $O(1)(mn + n^2)$, we conclude that *the total number of arithmetic operations when solving the Feasibility problem is polynomial in L .*

The last difficulty we need to handle is that the Ellipsoid Algorithm is a *Real Arithmetic* algorithm – it operates with real numbers, and not with rational ones, and assumes precise real arithmetics (exact arithmetic operations with reals, precise comparisons of reals and even precise taking of square root, since this operation appears in (6.2.5)), and thus polynomial in L total number of arithmetic operations we spoke about is the number of operations of *real arithmetics*. And what we want to get is an algorithm operating with rational operands and the cost of an arithmetic operation taking into account the bit sizes of the operands. Well, a straightforward, although tedious, analysis shows that we can achieve our goal – to approximate the optimal value of (6.3.1) within accuracy $\epsilon = \alpha/3$ in polynomial in L number of operations – when replacing *precise* real arithmetic operations with “actual” reals with *approximate* operations with *rounded* reals; specifically, it turns out that it suffices to operate with rationals with at most $O(1)nL$ binary digits before and after the dot, and to carry out the arithmetic operations and taking the square root approximately, within accuracy $O(1)2^{-nL}$. We can implement all these approximate arithmetic operations, and thus the entire computation, on a digital computer, with the “bitwise cost” of every approximate operation polynomial in nL (and thus in L), so that the total number of bitwise operations in course of the computation will be polynomial in L , as required.

All what remains is to justify **A** and **B**. Let us start with **A**. Since A is with trivial kernel, the polyhedral set $X = \{x : Ax \leq b\}$ does not contain lines (Proposition 2.3.5). Therefore *if X is nonempty, X contains an extreme point v* (Theorem 2.4.1). By algebraic characterization of extreme points (Proposition 2.3.2), we can choose from a_1, \dots, a_m n linearly independent vectors $\{a_i : i \in I\}$ such that $a_i^T v = b_i$ for $i \in I$. In other words, v is the unique solution of the linear system $A^I x = b^I$ of n linear equations with n variables and nonsingular matrix A^I such that $[A^I, b^I]$ is a submatrix in $[A, b]$. Applying Cramer rules, we conclude that

$$v_i = \frac{\Delta_i}{\Delta},$$

where $\Delta = \text{Det } A^I \neq 0$ and Δ_i is the determinant of the matrix A_i^I obtained from A^I by

replacing the i -th column with b^I . Now, Δ as the determinant of a matrix with integer entries, is an integer; being nonzero (A^I is nondegenerate!), its magnitude is at least 1. It follows that

$$|v_i| \leq |\Delta_i|.$$

Now, the determinant of an $n \times n$ matrix P_{ij} does not exceed the product of the $\|\cdot\|_1$ -lengths of its rows⁷. If now P is integral (as it is the case with A_i^I) and ℓ_{ij} is the bit length of P_{ij} , then $|P_{ij}| \leq 2^{\ell_{ij}-1}$ ⁸, and we see that $|\text{Det } P| \leq 2^{\sum_{i,j} \ell_{ij}}$. When $P = A_i^I$, $\sum_{i,j} \ell_{ij} \leq L$, since A_j^I is a submatrix of $[A, b]$, and we end up with $|\Delta_i| \leq 2^L$. The bottom line is that $\|v\|_\infty \leq 2^L$, and since $f(v) \leq 0$, **A** holds true with $O(1) = 1$.

Now let us prove **B**. Thus, assume that $\text{Opt} > 0$, and let us prove that Opt is not “too small.” Clearly,

$$\text{Opt} \geq \text{Opt}^+ = \inf_x f(x) = \inf_{[x;t]} \{t : A^+[x;t] := Ax - t\mathbf{1} \leq b\} \quad [\mathbf{1} = [1; \dots; 1]]$$

The LO program

$$\text{Opt}^+ = \min_{[x;t]} \{t : A^+[x;t] := Ax - t\mathbf{1} \leq b\} \quad (!)$$

clearly is feasible; we are in the situation when it is below bounded (indeed, its objective at every feasible solution is nonnegative, since otherwise Opt^+ would be negative, meaning that f attains somewhere negative values; but then, by already proved **A**, $\text{Opt} \leq 0$, which is not the case. Being feasible and bounded, (!) is solvable, meaning that f attains its minimum on \mathbf{R}^n ⁹ This minimum cannot be ≤ 0 , since then, by **A**, Opt would be nonpositive, which is not the case. The bottom line is that *LO program (!) has strictly positive optimal value Opt^+* .

Now, we claim that the $A^+ = [A, -\mathbf{1}]$ has trivial kernel along with A . Indeed, otherwise there exists $[\bar{x}; \bar{t}] \neq 0$ such that $A^+[\bar{x}; \bar{t}] = 0$, we have $\bar{t} \neq 0$, since otherwise $\bar{x} \neq 0$ and \bar{x} is in the kernel of A , and this kernel is trivial. We see that both $[\bar{x}; \bar{t}]$ and minus this vector are recessive directions of the nonempty feasible set X^+ of (!); along one of these directions, the objective strictly decreases (since $\bar{t} \neq 0$), meaning that (!) is below unbounded, which is not the case.

Since (!) is solvable with positive optimal value and the feasible set of this program does not contain lines, among the optimal solutions there exists one, let it be denoted $z = [x_*; t_*]$, which is a vertex of the feasible set of (!). Since $\text{Opt}^+ > 0$, we see that $t_* > 0$. Now we can act exactly as in the proof of **A**: since z is a vertex of the feasible set of (!), there exists an $(n+1) \times (n+2)$ submatrix $[\bar{A}, b]$ of the integral $m \times (n+2)$ matrix $[A^+, b]$ such that \bar{A} is an $(n+1) \times (n+1)$ nonsingular submatrix A^+ such that $\bar{A}[x_*; t_*] = \bar{b}$, whence, by Cramer rule and due to $t_* > 0$,

$$t_* = \frac{\Delta_*}{\Delta} = \frac{|\Delta_*|}{|\Delta|},$$

where Δ_* is the determinant of certain submatrix in $[\bar{A}, b]$, and Δ is $\text{Det } \bar{A}$. Since $t_* > 0$, $|\Delta_*| > 0$; being integral (A^+ is integral along with A, b), we therefore have $|\Delta_*| \geq 1$. Further, the

⁷Indeed, opening parentheses in the product $\prod_{i=1}^n (\sum_j |P_{ij}|)$, we get the sum of moduli of all “diagonal products” forming the determinant of P , and a lot of other nonnegative products. In fact, $|\text{Det } P|$ admits a better upper bound $\prod_{i=1}^n \sqrt{P_{i1}^2 + \dots + P_{in}^2}$ (Hadamard inequality; think how to prove it), but for our purposes, the previous, much worse, bound also is enough.

⁸Indeed, the number of bits in a representation of p_j is at least $\log_2(|P_{ij}| + 1)$ bits to store the binary digits of $|P_{ij}|$ plus one bit to store the sign of P_{ij} .

⁹In fact, our reasoning shows that every below bounded piecewise linear function attains its minimum on \mathbf{R}^n .

bit size of $[A^+, b]$ clearly is $O(1)L$, whence, by the same reasons as in the proof of **A**, $|\Delta| \leq 2^{O(1)L}$, in view of these observations, $t_* = \text{Opt}^+ \geq 2^{-O(1)L}$, whence, invoking (*), $\text{Opt} \geq 2^{-O(1)L}$, as claimed in **B**. \square

Step II: From checking feasibility to building a solution. The remaining steps are much simpler than the previous one. After we know how to check in polynomial time feasibility of a system S of m linear inequalities and equations, let us understand how to find its solution in the case when the system is feasible. It makes sense to denote the initial system by S_0 ; w.l.o.g., we can assume that the vectors a_i of coefficients in all constraints $a_i^T x \leq b_i$ constituting S_0 are nonzero. We start with checking feasibility of the system. If S_0 is infeasible, we terminate; if it is feasible, we take the first inequality $a^T x \leq b$ in the system, if any exists, convert it into the equality $a^T x = b$ and check feasibility of the resulting system. If it is feasible, it will be our new system S_1 , otherwise the hyperplane $a^T x = b$ does not intersect the feasible set of S_0 , and since this set is nonempty and is contained in the half-space $a^T x \leq b$, the inequality $a^T x \leq b$ in S_0 is in fact redundant: when we remove it from the system, the solution set does not change (why?). In the case in question we eliminate from S_0 the redundant inequality $a^T x \leq b$ and call the resulting system of inequalities and equalities S_1 . Note that in all cases S_1 is solvable, every solution to S_1 is a solution to S_0 . Besides this, the number of inequalities in S_1 is by 1 less than in S_0 .

We now repeat the outlined procedure with S_1 in the role of S_0 , thus obtaining a feasible system S_2 ; its solution set is contained in the one of the system S_1 , and thus — in the solution set of S_0 , and the number of inequalities in S_2 is by 2 less than in S_0 . Iteration this construction, we in at most m steps end up with a system S_ℓ which is feasible, contains only equality constraints, and every solution to this system solves S_0 as well. It remains to note that to solve a feasible system of linear *equality* constraints with integer or rational data is a simple Linear Algebra problem which is polynomially solvable. solving S_ℓ , we get a solution to the original system S_0 .

Now note that the bit sizes of all systems we deal with in the above process are of the same or even smaller bit size as the original system. Since feasibility checks take time polynomial in L , $m \leq L$, and the last system is polynomially solvable, the complexity of the entire process is polynomial in L .

Step III: Solving an LO program. Now we can solve in polynomial time an LO program

$$\max_x \{c^T x : Ax \leq b\} \quad (P)$$

with rational data. Let L be the bit size of the program. We start in checking in polynomial time whether the program is feasible; if it is not the case, we terminate with the correct claim “ (P) is infeasible,” otherwise check in polynomial time the feasibility of the dual problem

$$\min_\lambda \{b^T \lambda : \lambda \geq 0, A^T \lambda = c\} \quad (D)$$

which clearly has bit size $O(1)L$. If the dual problem is infeasible, we terminate with a correct claim “ (P) is unbounded.”

It remains to consider the case when both (P) and (D) are feasible and thus both are solvable (LO Duality Theorem). In this case, we put together the constraints of both programs

and augment them with the “zero duality gap” equation, thus arriving at the system of linear constraints

$$Ax \leq b; \lambda \geq 0; A^T \lambda = c; b^T \lambda = c^T x \quad (S)$$

in variables x, λ . By LO Optimality conditions, every feasible solution $[x; \lambda]$ to this system is comprised of optimal solutions to (P) and to (D) , so that (S) is feasible; the bit size of (S) clearly is $O(1)L$. Applying the construction from Step II, we can find a feasible solution to (S) , and thus optimal solutions to (P) and to (D) , in time polynomial in L . From the above description it is clear that overall computational effort of solving (P) also is polynomial in L . Khachiyan’s Theorem is proved. \square

Certifying insolvability in polynomial time. The proof of Khachiyan’s Theorem presents a CCM-polynomial time algorithm which, as applied to and LO program (P) with rational data, detects correctly whether the problem is infeasible, feasible and unbounded, or solvable; in the latter case, the algorithm produces an optimal solution to (P) and to the dual problem, thus certifying optimality of both the solutions. A natural question is, whether it is possible to get in polynomial time certificates for infeasibility/unboundedness of (P) , when the problem indeed is infeasible or unbounded. The answer is “yes.” Indeed, as in was explained in section 3.1.3 (see p. 110), in order to certify that (P) is infeasible, it suffices to point out a vector $\lambda \geq 0$ such that $A^T \lambda = 0$ and $b^T \lambda < 0$ (cf. (3.1.9)), or, which is the same (why?), a λ such that

$$\lambda \geq 0, A^T \lambda = 0, b^T \lambda \leq -1. \quad (S)$$

After infeasibility of (P) is detected, we can solve the latter system of linear inequalities and equations as explained in Step 2 above; note that we are in the situation when this system is solvable (since the certification scheme we are utilizing is complete). The data of (S) is rational, and its bit size is $O(1)L$, where L is the bit size of (P) . Applying construction from Step 2 to (S) , we get in polynomial time a solution to this system, thus certifying that (P) is infeasible.

After feasibility of (P) is detected and certified by presenting a feasible solution (which can be done by algorithm from Step 2) and the problem is found unbounded, in order to certify the latter conclusion it suffices to point out a recessive direction of (P) along which the objective of (P) increases (under circumstances, this is the same as to certify that (D) is infeasible). Thus, we need to find a solution y to the system

$$Ay \leq 0, c^T y > 0$$

(cf. (3.1.11)), or, which is the same, a solution to the system

$$Ay \leq 0, c^T y \geq 1 \quad (S')$$

which we already know to be solvable. By the same reasons as in the case of (S) , system (S') can be solved in a polynomial in L time.

The Ellipsoid Algorithm and computations

As we have seen, the Ellipsoid Algorithm, which by itself is a “universal” algorithm for solving convex optimization problems, implies a CCM-polynomial time solution algorithm for LO with

rational data; from the academic viewpoint, this algorithm outperforms dramatically the Simplex Method which has exponential worst-case complexity. In actual computations the situation is completely opposite: when solving real-life LO programs, Simplex Method dramatically outperforms the Ellipsoid one. The reason is simple: as a matter of fact, the Simplex Method never works according to its exponential complexity bound; the empirically observed upper bound on the number of pivoting steps is something like $3m$, where m is the number of equality constraints in a standard form LO program. In contrast to this, the EA works more or less according to its theoretical complexity bound (6.2.8) which says that in order to solve within an accuracy $\epsilon \ll 1$ a convex program with n variables, one should run $O(1)n^2 \ln(1/\epsilon)$ iterations of the method, with at least $O(n^2)$ arithmetic operations (a.o.) per iteration, which amounts to the total of at least $O(1)n^4 \ln(1/\epsilon)$ a.o. While being nearly independent of ϵ , this bound grows rapidly with n and becomes impractically large when $n = 1000$, meaning that problems with “just” 1000 variables (which is a small size in the LO scale) are beyond the “practical grasp” of the algorithm.

The fact that the EA “fails” when solving medium- and large-scale LO is quite natural — this algorithm is black-box-oriented and thus “does not know” how to utilize rich and specific structure of an LO program. Essentially, all what matters for the EA as applied to an LO program $\min_x \{c^T x : a_i^T x - b_i \leq 0, 1 \leq i \leq M\}$, is that the program has convex objective and constraints, and that the data of the problem allows to compute the values and the gradients of the objective and the constraints at a given point. Note that the Simplex Method is of completely different nature: it is not black-box-oriented, it works directly on program’s data, and it is “tailored” to LO: you just cannot apply this method to a problem with, say, convex quadratic objective and constraints.

The importance of the EA is primarily of academic nature — this is the algorithm which underlies the strongest known theoretical tractability results in Linear and Convex Optimization. Citing L. Lovasz, as far as efficient solvability of generic convex problems is concerned, the EA plays the role of an “existence theorem” rather than a tool of choice for practical computations.

In this respect, we should mention an additional important feature which did not attract our attention yet. Assume we are solving problem (6.2.1) – (6.2.3) with a simple – just linear – objective f (which, as we remember from lecture 1, is not an actual restriction) and a “complicated” feasible set X given by a finite, but perhaps very large, number M of linear inequality constraints $g_i(x) \leq 0$. Note that M does not directly affect the complexity characteristics of the algorithm; the constraints are “inside the Separation oracle,” and the EM simply does not “see” them. It follows that if the constraints defining X are “well organized,” so that given x , there is a way to identify in polynomial time a constraint, if any, which is violated at x , or to detect correctly that all the constraints are satisfied at x , the arithmetic complexity of a step of the EA will be polynomial. There are important optimization problems, some of them of combinatorial origin, which fit this framework; the EA, same as in the LO case, allows to demonstrate tractability of these problems (for examples, see [6]).

It should be added that while low-dimensional convex problems are of rather restricted applied interest, “restricted interest” is not the same as “no interest at all.” Low-dimensional (few tens of variables) convex problems do arise in many applications; whenever it happens, the EA becomes a “method of choice” allowing to get a high-accuracy solution in a quite reasonable time. The EA is especially well suited for solving low-dimensional convex problems with large number N of constraints in (6.2.3), since the complexity of the algorithm, even with a straightforward

implementation of the Separation oracle (“given a query point, look through all the constraints to find a violated one or to conclude that all of them are satisfied”), is just linear in N .

Part IV

From Linear to Semidefinite Optimization: Interior Point Methods

Lecture 7

Conic Programming and Interior Point Methods in LO and Semidefinite Optimization

The EA-based Khachiyan’s polynomial time algorithm for solving LO program with rational data is of academic interest only; in the real life LO, it is by far outperformed by “theoretically bad” pivoting time algorithms. Nevertheless, the discovery of polynomial time algorithm for LO triggered an intensive search for LO techniques which are both theoretically *and practically* efficient. The breakthroughs in this direction due to N. Karmarkar (’84), J. Renegar (’86) and C. Gonzaga (’86) led to development of novel *Interior Point* polynomial time algorithms for LO which were further extended onto nonlinear “well-structured” convex problems. The common name for the resulting Convex Programming techniques is *Interior Point Methods* (IPMs); this name is aimed at stressing the fact that even in the LO case, the methods, in contrast to the simplex-type ones, move along the interior of the feasible polyhedron rather than along its vertices.

As far as LO is concerned, the state-of-the-art IPM’s are quite competitive with the simplex-type algorithms. It suffices to say that they are the default options in modern commercial LO solvers.

While the very first IPMs were designed for LO, it turned out that their intrinsic nature has nothing to do with Linear Optimization, and the IPM approach can be extended, essentially, onto all convex programs; the corresponding theory was proposed in [10] and is now the standard way to treat IPM’s. In [10] and in the subsequent IPM particular, it was discovered, in particular, that

- the most powerful IPM’s are associated with representation of convex problems in a specific *conic form*, pretty similar to the form of a usual LO program. Aside of algorithmic issues, conic representation of convex programs allows for very instructive reformulation of convex programming theory, most notably, of its duality-related part;
- there exist three intrinsically very close to each other generic conic problems – Linear, Conic Quadratic and Semidefinite Optimization; taken together, these three problems allow to handle nearly all convex optimization models arising in applications. The specific intrinsic nature of these three problems, along with other important consequences, allows for a significant enrichment (primarily, due to Nesterov and Todd, [11, 12]) of the general

IPM theory, on one hand, and for unified and relatively non-technical presentation of the basic part of this theory, on the other hand.

While our course is devoted to LO, it would be a pity to restrict ourselves with LO also when speaking about Interior Point Methods. Indeed, at a low “setup cost” of learning Conic Programming (a knowledge which is highly valuable by its own right) we can “kill two birds with one stone” – to become acquainted with the basic IPM methods for Linear and Semidefinite Optimization¹. To the best of our understanding, the only shortcoming of this course of actions is that while we will be able to understand *what* is going on, we will be unable to explain *why* we act as we are acting and where some “miracles” to be met come from. Answering these “why and where” questions would require long excursions to the general theory of IPM methods as presented in [10, 13], which would be too much for an introductory course on LO.

The course of our actions is as follows: we start with acquaintance with Conic Programming, with emphasis on Conic Programming Duality Theorem and investigating “expressive abilities” of the three most important generic conic problems, those of Linear, Conic Quadratic and Semidefinite Optimization². We will then become acquainted with the basic theory of IPM’s for SDO (and thus for LO, which, as we shall see in the mean time, is a simple particular case of SDO).

7.1 Conic Programming

7.1.1 Cones in Euclidean Spaces

Euclidean spaces

A *Euclidean space* is a finite dimensional linear space over reals equipped with an *inner product* $\langle x, y \rangle_E$ real-valued function of $x, y \in E$ which is

- symmetric ($\langle x, y \rangle_E \equiv \langle y, x \rangle_E$),
- bilinear ($\langle \lambda u + \mu v, y \rangle_E = \lambda \langle u, y \rangle_E + \mu \langle v, y \rangle_E$, and similarly w.r.t. the second argument) and
- positive definite ($\langle x, x \rangle_E > 0$ whenever $x \neq 0$).

In the sequel, we usually shorten $\langle x, y \rangle_E$ to $\langle x, y \rangle$, provided that E is fixed by the context.

Example: The standard Euclidean space \mathbf{R}^n . This space is comprised of n -dimensional real column vectors with the standard coordinate-wise linear operations and the inner product $\langle x, y \rangle_{\mathbf{R}^n} = x^T y$. \mathbf{R}^n is a universal example of an Euclidean space: for every Euclidean n -dimensional space $(E, \langle \cdot, \cdot \rangle_E)$ there exists a one-to-one linear mapping $x \mapsto Ax : \mathbf{R}^n \rightarrow E$ such that $x^T y \equiv \langle Ax, Ay \rangle_E$. All we need in order to build such a mapping, is to find an *orthonormal basis* e_1, \dots, e_n , $n = \dim E$, in E , that is, a basis such that $\langle e_i, e_j \rangle_E = \delta_{ij} \equiv \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases}$; such a basis always exists. Given an orthonormal basis $\{e_i\}_{i=1}^n$, a one-to-one mapping $A : \mathbf{R}^n \rightarrow E$ preserving the inner product is given by $Ax = \sum_{i=1}^n x_i e_i$.

¹In our unified treatment, we are enforced to omit Conic Quadratic Optimization, where the IPM constructions, intrinsically the same as in LO and SDO, would require different notation.

²Since we already know what are expressive abilities of LO, our focus here will be on how these abilities extend when passing from LO to CQO and SDO.

Example: The space $\mathbf{R}^{m \times n}$ of $m \times n$ real matrices with the Frobenius inner product. The elements of this space are $m \times n$ real matrices with the standard linear operations and the inner product $\langle A, B \rangle_F = \text{Tr}(AB^T) = \sum_{i,j} A_{ij}B_{ij}$.

Example: The space \mathbf{S}^n of $n \times n$ real symmetric matrices with the Frobenius inner product. This is the subspace of $\mathbf{R}^{n \times n}$ comprised of all symmetric $n \times n$ matrices; the inner product is inherited from the embedding space. Of course, for symmetric matrices, this product can be written down without transposition:

$$A, B \in \mathbf{S}^n \Rightarrow \langle A, B \rangle_F = \text{Tr}(AB) = \sum_{i,j} A_{ij}B_{ij}.$$

The last example explains why we need Euclidean spaces instead of sticking to \mathbf{R}^n with the standard inner product: we intend in the future to work also with the Euclidean space $\mathbf{S}^n, \langle \cdot, \cdot \rangle_F$; while it is possible to identify it with \mathbf{R}^N , $N = \frac{n(n+1)}{2}$, equipped with the standard inner product, it would be complete disaster to work with “vector representations” of matrices from \mathbf{S}^n instead of working with these matrices directly.

Linear forms on Euclidean spaces

Every homogeneous linear form $f(x)$ on a Euclidean space $(E, \langle \cdot, \cdot \rangle_E)$ can be represented in the form $f(x) = \langle e_f, x \rangle_E$ for certain vector $e_f \in E$ uniquely defined by $f(\cdot)$. The mapping $f \mapsto e_f$ is a one-to-one linear mapping of the space of linear forms on E onto E .

Conjugate mapping

Let $(E, \langle \cdot, \cdot \rangle_E)$ and $(F, \langle \cdot, \cdot \rangle_F)$ be Euclidean spaces. For a linear mapping $A : E \rightarrow F$ and every $f \in F$, the function $\langle Ae, f \rangle_F$ is a linear function of $e \in E$ and as such it is representable as $\langle e, A^*f \rangle_E$ for certain uniquely defined vector $A^*f \in E$. It is immediately seen that the mapping $f \mapsto A^*f$ is a linear mapping of F into E ; the characteristic identity specifying this mapping is

$$\langle Ae, f \rangle_F = \langle e, A^*f \rangle_E \quad \forall (e \in E, f \in F).$$

The mapping A^* is called *conjugate* to A . It is immediately seen that the conjugation is a linear operation with the properties $(A^*)^* = A$, $(AB)^* = B^*A^*$. If $\{e_j\}_{j=1}^m$ and $\{f_i\}_{i=1}^n$ are orthonormal bases in E, F , then every linear mapping $A : E \rightarrow F$ can be associated with the matrix $[a_{ij}]$ (“matrix of the mapping in the pair of bases in question”) according to the identity

$$A \sum_{j=1}^m x_j e_j = \sum_i \left[\sum_j a_{ij} x_j \right] f_i$$

(in other words, a_{ij} is the i -th coordinate of the vector Ae_j in the basis f_1, \dots, f_n). With this representation of linear mappings by matrices, the matrix representing A^* in the pair of bases $\{f_i\}$ in the argument and $\{e_j\}$ in the image spaces of A^* is the transpose of the matrix representing A in the pair of bases $\{e_j\}, \{f_i\}$.

Cones in Euclidean spaces

A nonempty subset \mathbf{K} of a Euclidean space $(E, \langle \cdot, \cdot \rangle_E)$ is called a cone, if it is a convex set comprised of rays emanating from the origin, or, equivalently, whenever $t_1, t_2 \geq 0$ and $x_1, x_2 \in \mathbf{K}$, we have $t_1 x_1 + t_2 x_2 \in \mathbf{K}$.

A cone \mathbf{K} is called *regular*, if it is closed, possesses a nonempty interior and is *pointed* — does not contain lines, or, which is the same, is such that $a \in \mathbf{K}$, $-a \in \mathbf{K}$ implies that $a = 0$.

Dual cone. If \mathbf{K} is a cone in a Euclidean space $(E, \langle \cdot, \cdot \rangle_E)$, then the set

$$\mathbf{K}^* = \{e \in E : \langle e, h \rangle_E \geq 0 \forall h \in \mathbf{K}\}$$

also is a cone called the cone *dual* to \mathbf{K} . The dual cone always is closed. The cone dual to dual is the closure of the original cone: $(\mathbf{K}^*)^* = \text{cl } \mathbf{K}$; in particular, $(\mathbf{K}^*)^* = \mathbf{K}$ for every closed cone \mathbf{K} . For a closed cone \mathbf{K} , the cone \mathbf{K}^* possesses a nonempty interior iff \mathbf{K} is pointed, and \mathbf{K}^* is pointed iff \mathbf{K} possesses a nonempty interior; in particular, \mathbf{K} is regular iff \mathbf{K}^* is so.

Example: Nonnegative ray and nonnegative orthants. The simplest one-dimensional cone is the nonnegative ray $\mathbf{R}_+ = \{t \geq 0\}$ on the real line \mathbf{R}^1 . The simplest cone in \mathbf{R}^n is the *nonnegative orthant* $\mathbf{R}_+^n = \{x \in \mathbf{R}^n : x_i \geq 0, 1 \leq i \leq n\}$. This cone is regular and self-dual: $(\mathbf{R}_+^n)^* = \mathbf{R}_+^n$.

Example: Lorentz cone \mathbf{L}^n . The cone \mathbf{L}^n “lives” in \mathbf{R}^n and is comprised of all vectors $x = [x_1; \dots; x_n] \in \mathbf{R}^n$ such that $x_n \geq \sqrt{\sum_{j=1}^{n-1} x_j^2}$; same as \mathbf{R}_+^n , the Lorentz cone is regular and self-dual.

By definition, $\mathbf{L}^1 = \mathbf{R}_+$ is the nonnegative orthant; this is in full accordance with the “general” definition of a Lorentz cone combined with the standard convention “a sum over an empty set of indices is 0.”

Example: Semidefinite cone \mathbf{S}_+^n . The cone \mathbf{S}_+^n “lives” in the Euclidean space \mathbf{S}^n of $n \times n$ symmetric matrices equipped with the Frobenius inner product. The cone is comprised of all $n \times n$ symmetric *positive semidefinite* matrices A , i.e., matrices $A \in \mathbf{S}^n$ such that $x^T A x \geq 0$ for all $x \in \mathbf{R}^n$, or, equivalently, such that all eigenvalues of A are nonnegative. Same as \mathbf{R}_+^n and \mathbf{L}^n , the cone \mathbf{S}_+^n is regular and self-dual.

Finally, we remark that the direct product of regular cones is regular, and the dual of this product is the direct product of the duals of the original cones.

When checking this absolutely evident statement, you should take into account how we take the direct product of Euclidean spaces, since without a Euclidean structure on the product of the Euclidean spaces embedding the cones we are multiplying, the claim about the dual of a direct product of cones becomes senseless. The Euclidean structure on the direct product $E = E_1 \times \dots \times E_m$ of Euclidean spaces is defined as follows: vectors from E , by the definition of direct product, are ordered tuples (x^1, \dots, x^m) with $x^i \in E_i$, and we set

$$\langle (x^1, \dots, x^m), (y^1, \dots, y^m) \rangle_E = \sum_{i=1}^m \langle x^i, y^i \rangle_{E_i}.$$

with this definition, a direct product of the spaces $\mathbf{R}^{n_1}, \dots, \mathbf{R}^{n_m}$ equipped with the standard inner products is $\mathbf{R}^{n_1 + \dots + n_m}$, also equipped with the standard inner product, and the direct product of the spaces $\mathbf{S}^{n_1}, \dots, \mathbf{S}^{n_m}$ equipped with the Frobenius inner products can be viewed as the space $\mathbf{S}^{n_1, \dots, n_m}$ of *block-diagonal* symmetric matrices with m diagonal blocks of sizes n_1, \dots, n_m , equipped with the Frobenius inner product.

We have made several not self-evident claims, and here are their proofs (we slightly alter the order of claims and, aside of the latter item, assume w.l.o.g. that the Euclidean space in question is \mathbf{R}^n with the standard inner product).

- For every cone K , one has K^* is a closed cone, and $(K^*)^* = \text{cl } K$. The closedness of a dual cone is evident, same as the facts that $\text{cl } K$ is a closed cone such that $(\text{cl } K)^* = K^*$. Besides this, we clearly have $(K^*)^* \supset \text{cl } K$. To prove that the latter \supset is in fact $=$, assume that this is not the case, so that $(K^*)^*$ contains a vector $x \notin \text{cl } K$. By Separation Theorem for Convex Sets (Theorem 2.4.3), there exists a linear form $e^T w$ such that $e^T x < \inf_{y \in \text{cl } K} e^T y = \inf_{y \in K} e^T y$. But the infimum of a linear form $e^T y$ on a cone K is either $-\infty$ (this is the case when e has negative inner product with certain vector from K , i.e., when $e \in K^*$), or is 0 (this is the case when $e \in K^*$). We are in the case when the infimum $\inf_{y \in K} e^T y$ is $> e^T x$ and thus is finite, whence $e \in K^*$, the infimum is 0 and thus $e^T x < 0$, which impossible due to $x \in (K^*)^*$. \square

- For every cone \mathbf{K} , \mathbf{K}^* is pointed iff $\text{int } \mathbf{K} \neq \emptyset$. Indeed, if $\text{int } \mathbf{K}$ is nonempty and thus contains a ball B of radius $r > 0$, and $h, -h \in \mathbf{K}^*$, then the linear form $h^T x$ should be both nonnegative and nonpositive on B ; but a vector h can be orthogonal to all vectors from a ball of positive radius iff $h = 0$. Thus, \mathbf{K}^* is pointed. On the other hand, if $\text{int } \mathbf{K} = \emptyset$, then $\text{Aff}(\mathbf{K}) \neq \mathbf{R}^n$ due to Theorem 2.1.3. Since $0 \in \mathbf{K}$, $\text{Aff}(\mathbf{K})$ is a linear subspace in \mathbf{R}^n , and since it differs from \mathbf{R}^n , its orthogonal complement does not reduce to $\{0\}$. In other words, there exists $h \neq 0$ which is orthogonal to $\text{Aff}(\mathbf{K})$, whence $\pm h \in \mathbf{K}^*$, and the latter cone is not pointed. \square

- For a closed cone \mathbf{K} , \mathbf{K}^* has a nonempty interior iff \mathbf{K} is pointed. This is readily given by the previous item due to $\mathbf{K} = (\mathbf{K}^*)^*$.
- The nonnegative orthant \mathbf{R}_+^n is regular and self-dual. This is evident.
- The Lorentz cone \mathbf{L}^n is regular and self-dual. Regularity is evident. To prove self-duality, we should verify that given $[u; t]$ with $u \in \mathbf{R}^{n-1}$, the relation $[u; t]^T [v; \tau] \geq 0$ holds true for all $[v; \tau]$ with $\tau \geq \|v\|_2$ iff $t \geq \|u\|_2$, or, which is the same, to verify that for every vector $[u; t]$ one has $\inf_{[v; \tau]: \|v\|_2 \leq \tau} [u; t]^T [v; \tau] \geq 0$ iff $t \geq \|u\|_2$. This is immediate, since

$$\inf_{[v; \tau]: \|v\|_2 \leq \tau} [u; t]^T [v; \tau] = \inf_{\tau \geq 0} \left[t\tau + \inf_{v: \|v\|_2 \leq \tau} u^T v \right] = \inf_{\tau \geq 0} \tau[t - \|u\|_2]. \quad \square$$

- The cone \mathbf{S}_+^n of positive semidefinite matrices in the space of \mathbf{S}^n of symmetric $n \times n$ matrices equipped with the Frobenius inner product is regular and self-dual. Regularity is evident. To prove self-duality we should verify that if $B \in \mathbf{S}^n$, then $\text{Tr}(BX) \equiv \langle B, X \rangle_{\mathbf{S}^n} \geq 0$ for all $X \in \mathbf{S}_+^n$ iff $B \in \mathbf{S}_+^n$. In one direction: setting $X = xx^T$ with $x \in \mathbf{R}^n$, we get $X \succeq 0$. Thus, if $B \in (\mathbf{S}_+^n)^*$, then $\text{Tr}(xx^T B) = \text{Tr}(x^T Bx) = x^T Bx \geq 0$ for all x , and thus $B \in \mathbf{S}_+^n$ ³. In the opposite direction: When $B \in \mathbf{S}_+^n$, then, by the Eigenvalue Decomposition Theorem, $B = \sum_{i=1}^n \lambda_i e_i e_i^T$ with orthonormal e_1, \dots, e_n and nonnegative λ_i

³We have used a simple and useful identity: when P and Q are matrices such that PQ makes sense and is a square matrix, so that $\text{Tr}(PQ)$ makes sense, then $\text{Tr}(PQ) = \text{Tr}(QP)$ (why?).

(the latter in fact are eigenvalues of B). It follows that when $X \in \mathbf{S}_+^n$, then $\text{Tr}(BX) = \sum_i \lambda_i \text{Tr}(e_i e_i^T X) = \sum_i \lambda_i e_i^T X e_i$; when $X \in \mathbf{S}_+^n$, and all terms in the resulting sum are nonnegative, and thus $\text{Tr}(BX) \geq 0$ whenever $X \in \mathbf{S}_+^n$, that is, $B \in (\mathbf{S}_+^n)^*$.

7.1.2 Conic Problems

A *conic program* is an optimization program of the form

$$\text{Opt}(P) = \min_x \left\{ \langle c, x \rangle_E : \begin{array}{l} A_i x - b_i \in \mathbf{K}_i, i = 1, \dots, m, \\ R x = r \end{array} \right\} \quad (P)$$

where

- $(E, \langle \cdot, \cdot \rangle_E)$ is a Euclidean space of *decision vectors* x and $c \in E$ is the *objective*;
- $A_i, 1 \leq i \leq m$, are linear maps from E into Euclidean spaces $(F_i, \langle \cdot, \cdot \rangle_{F_i})$, $b_i \in F_i$ and $\mathbf{K}_i \subset F_i$ are regular cones;
- R is a linear mapping from E into a Euclidean space $(F, \langle \cdot, \cdot \rangle_F)$ and $r \in F$.

A relation $a - b \in \mathcal{K}$, where \mathcal{K} is a regular cone, is often called *conic inequality* between a and b and is denoted $a \geq_{\mathbf{K}} b$; such a relation indeed preserves the major properties of the usual coordinate-wise vector inequality \geq . While in the sequel we do not use the notation $A \geq_{\mathbf{K}} b$, we do call a constraint of the form $Ax - b \in \mathbf{K}$ a *conic inequality constraint* or simply *conic constraint*.

Note that we can rewrite (P) equivalently as a conic program involving a *single cone* $\mathbf{K} = \mathbf{K}_1 \times \dots \times \mathbf{K}_m$, specifically, as

$$\min_x \left\{ \langle c, x \rangle_E : \begin{array}{l} Ax - b \in \mathbf{K} = \mathbf{K}_1 \times \dots \times \mathbf{K}_m, \\ R x = r \end{array} \right\}, \quad Ax - b = \begin{bmatrix} A_1 x - b_1 \\ \vdots \\ A_m x - b_m \end{bmatrix}; \quad (P')$$

Since the direct product of several regular cones clearly is regular as well, (P') indeed is a legitimate “single cone” conic program.

Examples: Linear, Conic Quadratic and Semidefinite Optimization. We will be especially interested in the three generic conic problems as follows:

- *Linear Optimization*, or *Linear Programming*: this is the family of all conic programs associated with nonnegative orthants \mathbf{R}_+^m , that is, the family of all usual LPs $\min_x \{c^T x : Ax - b \geq 0\}$;
- *Conic Quadratic Optimization*, or *Conic Quadratic Programming*, or *Second Order Cone Programming*: this is the family of all conic programs associated with the cones that are *finite direct products* of Lorentz cones, that is, the conic programs of the form

$$\min_x \left\{ c^T x : [A_1; \dots; A_m]x - [b_1; \dots; b_m] \in \mathbf{L}^{k_1} \times \dots \times \mathbf{L}^{k_m} \right\}$$

where A_i are $k_i \times \dim x$ matrices and $b_i \in \mathbf{R}^{k_i}$. The “Mathematical Programming” form of such a program is

$$\min_x \left\{ c^T x : \|\bar{A}_i x - \bar{b}_i\|_2 \leq \alpha_i^T x - \beta_i, 1 \leq i \leq m \right\},$$

where $A_i = [\bar{A}_i; \alpha_i^T]$ and $b_i = [\bar{b}_i; \beta_i]$, so that α_i is the last row of A_i , and β_i is the last entry of b_i ;

- *Semidefinite Optimization*, or *Semidefinite Programming*: this is the family of all conic programs associated with the cones that are *finite direct products* of Semidefinite cones, that is, the conic programs of the form

$$\min_x \left\{ c^T x : A_i^0 + \sum_{j=1}^{\dim x} x_j A_i^j \succeq 0, 1 \leq i \leq m \right\}, \quad (*)$$

where A_i^j are symmetric matrices of appropriate sizes.

7.1.3 Conic Duality

Conic duality — derivation

The origin of conic duality is the desire to find a systematic way to bound from below the optimal value in a conic program (P) . This way is based on *linear aggregation* of the constraints of (P) , namely, as follows. Let $y_i \in \mathbf{K}_i^*$ and $z \in F$. By the definition of the dual cone, for every x feasible for (P) we have

$$\langle A_i^* y_i, x \rangle_E - \langle y_i, b_i \rangle_{F_i} \equiv \langle y_i, Ax_i - b_i \rangle_{F_i} \geq 0, 1 \leq i \leq m,$$

and of course

$$\langle R^* z, x \rangle_E - \langle z, r \rangle_F = \langle z, Rx - r \rangle_F = 0.$$

Summing up the resulting inequalities, we get

$$\langle R^* z + \sum_i A_i^* y_i, x \rangle_E \geq \langle z, r \rangle_F + \sum_i \langle y_i, b_i \rangle_{F_i}. \quad (C)$$

By its origin, this scalar linear inequality on x is a consequence of the constraints of (P) , that is, it is valid for all feasible solutions x to (P) . It may happen that the left hand side in this inequality is, identically in $x \in E$, equal to the objective $\langle c, x \rangle_E$; this happens iff

$$R^* z + \sum_i A_i^* y_i = c.$$

Whenever it is the case, the right hand side of (C) is a valid lower bound on the optimal value of (P) . The dual program is nothing but the program

$$\text{Opt}(D) = \max_{z, \{y_i\}} \left\{ \langle z, r \rangle_F + \sum_i \langle y_i, b_i \rangle_{F_i} : \begin{array}{l} y_i \in \mathbf{K}_i^*, 1 \leq i \leq m, \\ R^* z + \sum_i A_i^* y_i = c \end{array} \right\} \quad (D)$$

of maximizing this lower bound.

Remark: Note that the construction we have presented is completely similar to the one we used in section 3.2.1 to derive the LO dual of a given LO program. The latter is the particular case of (P) where all \mathbf{K}_i are nonnegative orthants of various dimensions, or, which is the same the cone \mathbf{K} in (P') is a nonnegative orthant. The only minor differences stem from the facts that now it is slightly more convenient to write the primal program as a minimization one, while

in the LO we preferred to write down the primal program as a maximization one. Modulo this absolutely unessential difference, our derivation of the dual of an LO program is nothing but our present construction as applied to the case when all \mathbf{K}_i are nonnegative rays. In fact, a reader will see that all Conic Duality constructions and results we are about to present mirror already known to us constructions and results of LO Duality.

Coming back to conic dual of a conic program, observe that by the origin of the dual we have

Weak Duality: *One has $\text{Opt}(D) \leq \text{Opt}(P)$.*

Besides this, we see that (D) is a conic program. A nice and important fact is that *conic duality is symmetric*.

Symmetry of Duality: *The conic dual to (D) is (equivalent to) (P) .*

Proof:

In order to apply to (D) the outlined recipe for building the conic dual, we should rewrite (D) as a *minimization* program

$$-\text{Opt}(D) = \min_{z, \{y_i\}} \left\{ \langle z, -r \rangle_F + \sum_i \langle y_i, -b_i \rangle_{F_i} : \begin{array}{l} y_i \in \mathbf{K}_i^*, 1 \leq i \leq m \\ R^*z + \sum_i A_i^* y_i = c \end{array} \right\}; \quad (D')$$

the corresponding space of decision vectors is the direct product $F \times F_1 \times \dots \times F_m$ of Euclidean spaces equipped with the inner product

$$\langle [z; y_1, \dots, y_m], [z'; y'_1, \dots, y'_m] \rangle = \langle z, z' \rangle_F + \sum_i \langle y_i, y'_i \rangle_{F_i}.$$

The above “duality recipe” as applied to (D') reads as follows: pick weights $\eta_i \in (\mathbf{K}_i^*)^* = \mathbf{K}_i$ and $\zeta \in E$, so that the scalar inequality

$$\underbrace{\langle \zeta, R^*z + \sum_i A_i^* y_i \rangle_E + \sum_i \langle \eta_i, y_i \rangle_{F_i}}_{= \langle R\zeta, z \rangle_F + \sum_i \langle A_i \zeta + \eta_i, y_i \rangle_{F_i}} \geq \langle \zeta, c \rangle_E \quad (C')$$

in variables $z, \{y_i\}$ is a consequence of the constraints of (D') , and impose on the “aggregation weights” $\zeta, \{\eta_i \in \mathbf{K}_i\}$ an additional restriction that the left hand side in this inequality is, identically in $z, \{y_i\}$, equal to the objective of (D') , that is, the restriction that

$$R\zeta = -r, A_i \zeta + \eta_i = -b_i, 1 \leq i \leq m,$$

and maximize under this restriction the right hand side in (C') , thus arriving at the program

$$\max_{\zeta, \{\eta_i\}} \left\{ \langle c, \zeta \rangle_E : \begin{array}{l} \mathbf{K}_i \ni \eta_i = A_i[-\zeta] - b_i, 1 \leq i \leq m \\ R[-\zeta] = r \end{array} \right\}.$$

Substituting $x = -\zeta$, the resulting program, after eliminating η_i variables, is nothing but

$$\max_x \left\{ -\langle c, x \rangle_E : \begin{array}{l} A_i x - b_i \in \mathbf{K}_i, 1 \leq i \leq m \\ Rx = r \end{array} \right\},$$

which is equivalent to (P) . □

Conic Duality Theorem

A conic program (P) is called *strictly feasible*, if it admits a *strictly feasible* solution, that is, a feasible solution \bar{x} such that $A_i\bar{x} - b_i \in \text{int } \mathbf{K}_i$, $i = 1, \dots, m$.

Conic Duality Theorem is the following statement resembling very much the Linear Programming Duality Theorem:

Theorem 7.1.1 [Conic Duality Theorem] *Consider a primal-dual pair of conic programs (P) , (D) . Then*

- (i) [Weak Duality] *One has $\text{Opt}(D) \leq \text{Opt}(P)$.*
- (ii) [Symmetry] *The duality is symmetric: (D) is a conic program, and the program dual to (D) is (equivalent to) (P) .*
- (iii) [Strong Duality] *If one of the programs (P) , (D) is strictly feasible and bounded, then the other program is solvable, and $\text{Opt}(P) = \text{Opt}(D)$.*

If both the programs are strictly feasible, then both are solvable with equal optimal values.

Proof:

We have already verified Weak Duality and Symmetry. Let us prove the first claim in Strong Duality. By Symmetry, we can restrict ourselves to the case when the strictly feasible and bounded program is (P) .

Consider the following two sets in the Euclidean space $G = \mathbf{R} \times F \times F_1 \times \dots \times F_m$:

$$\begin{aligned} T &= \{[t; z; y_1; \dots; y_m] : \exists x : t = \langle c, x \rangle_E; y_i = A_i x - b_i, 1 \leq i \leq m; \\ &\quad z = Rx - r\}, \\ S &= \{[t; z; y_1; \dots; y_m] : t < \text{Opt}(P), y_1 \in \mathbf{K}_1, \dots, y_m \in \mathbf{K}_m, z = 0\}. \end{aligned}$$

The sets T and S clearly are convex and nonempty; observe that they do not intersect. Indeed, assuming that $[t; z; y_1; \dots; y_m] \in S \cap T$, we should have $t < \text{Opt}(P)$, and $y_i \in \mathbf{K}_i$, $z = 0$ (since the point is in S), and at the same time for certain $x \in E$ we should have $t = \langle c, x \rangle_E$ and $A_i x - b_i = y_i \in \mathbf{K}_i$, $Rx - r = z = 0$, meaning that there exists a feasible solution to (P) with the value of the objective $< \text{Opt}(P)$, which is impossible. Since the convex and nonempty sets S and T do not intersect, they can be separated by a linear form (Theorem 2.4.3): there exists $[\tau; \zeta; \eta_1; \dots; \eta_m] \in G = \mathbf{R} \times F \times F_1 \times \dots \times F_m$ such that

$$\begin{aligned} (a) \quad & \sup_{[t; z; y_1; \dots; y_m] \in S} \langle [\tau; \zeta; \eta_1; \dots; \eta_m], [t; z; y_1; \dots; y_m] \rangle_G \\ & \leq \inf_{[t; z; y_1; \dots; y_m] \in T} \langle [\tau; \zeta; \eta_1; \dots; \eta_m], [t; z; y_1; \dots; y_m] \rangle_G, \\ (b) \quad & \inf_{[t; z; y_1; \dots; y_m] \in S} \langle [\tau; \zeta; \eta_1; \dots; \eta_m], [t; z; y_1; \dots; y_m] \rangle_G \\ & < \sup_{[t; z; y_1; \dots; y_m] \in T} \langle [\tau; \zeta; \eta_1; \dots; \eta_m], [t; z; y_1; \dots; y_m] \rangle_G, \end{aligned}$$

or, which is the same,

$$\begin{aligned} (a) \quad & \sup_{t < \text{Opt}(P), y_i \in \mathbf{K}_i} [\tau t + \sum_i \langle \eta_i, y_i \rangle_{F_i}] \\ & \leq \inf_{x \in E} [\tau \langle c, x \rangle_E + \langle \zeta, Rx - r \rangle_F + \sum_i \langle \eta_i, A_i x - b_i \rangle_{F_i}], \\ (b) \quad & \inf_{t < \text{Opt}(P), y_i \in \mathbf{K}_i} [\tau t + \sum_i \langle \eta_i, y_i \rangle_{F_i}] \\ & < \sup_{x \in E} [\tau \langle c, x \rangle_E + \langle \zeta, Rx - r \rangle_F + \sum_i \langle \eta_i, A_i x - b_i \rangle_{F_i}]. \end{aligned} \tag{7.1.1}$$

Since the left hand side in (7.1.1.a) is finite, we have

$$\tau \geq 0, -\eta_i \in \mathbf{K}_i^*, 1 \leq i \leq m, \quad (7.1.2)$$

whence the left hand side in (7.1.1.a) is equal to $\tau \text{Opt}(P)$. Since the right hand side in (7.1.1.a) is finite, we have

$$R^*\zeta + \sum_i A_i^* \eta_i + \tau c = 0 \quad (7.1.3)$$

and the right hand side in (a) is $\langle -\zeta, r \rangle_F - \sum_i \langle \eta_i, b_i \rangle_{F_i}$, so that (7.1.1.a) reads

$$\tau \text{Opt}(P) \leq \langle -\zeta, r \rangle_F - \sum_i \langle \eta_i, b_i \rangle_{F_i}. \quad (7.1.4)$$

We claim that $\tau > 0$. Believing in our claim, let us extract from it Strong Duality. Indeed, setting $y_i = -\eta_i/\tau$, $z = -\zeta/\tau$, (7.1.2), (7.1.3) say that $z, \{y_i\}$ is a feasible solution for (D), and by (7.1.4) the value of the dual objective at this dual feasible solution is $\geq \text{Opt}(P)$. By Weak Duality, this value cannot be larger than $\text{Opt}(P)$, and we conclude that our solution to the dual is in fact an optimal one, and that $\text{Opt}(P) = \text{Opt}(D)$, as claimed.

It remains to prove that $\tau > 0$. Assume this is not the case; then $\tau = 0$ by (7.1.2). Now let \bar{x} be a strictly feasible solution to (P). Taking inner product of both sides in (7.1.3) with \bar{x} , we have

$$\langle \zeta, R\bar{x} \rangle_F + \sum_i \langle \eta_i, A_i \bar{x} \rangle_{F_i} = 0,$$

while (7.1.4) reads

$$-\langle \zeta, r \rangle_F - \sum_i \langle \eta_i, b_i \rangle_{F_i} \geq 0.$$

Summing up the resulting inequalities and taking into account that \bar{x} is feasible for (P), we get

$$\sum_i \langle \eta_i, A_i \bar{x} - b_i \rangle \geq 0.$$

Since $A_i \bar{x} - b_i \in \text{int } \mathbf{K}_i$ and $\eta_i \in -\mathbf{K}_i^*$, the inner products in the left hand side of the latter inequality are nonpositive, and i -th of them is zero iff $\eta_i = 0$; thus, the inequality says that $\eta_i = 0$ for all i . Adding this observation to $\tau = 0$ and looking at (7.1.3), we see that $R^*\zeta = 0$, whence $\langle \zeta, Rx \rangle_F = 0$ for all x and, in particular, $\langle \zeta, r \rangle_F = 0$ due to $r = R\bar{x}$. The bottom line is that $\langle \zeta, Rx - r \rangle_F = 0$ for all x . Now let us look at (7.1.1.b). Since $\tau = 0$, $\eta_i = 0$ for all i and $\langle \zeta, Rx - r \rangle_F = 0$ for all x , both sides in this inequality are equal to 0, which is impossible. We arrive at a desired contradiction.

We have proved the first claim in Strong Duality. The second claim there is immediate: if both (P), (D) are strictly feasible, then both programs are bounded as well by Weak Duality, and thus are solvable with equal optimal values by the already proved part of Strong Duality. \square

Remark: The Conic Duality Theorem is a bit weaker than its LO counterpart: where in the LO case plain feasibility was enough, now strong feasibility is required. It can be easily demonstrated by examples that this difference stems from the essence of the matter rather than being a shortcoming of our proofs. Indeed, it can be easily demonstrated by examples that in the case of non-polyhedral cones various “pathologies” can take place, e.g.

- (P) can be strictly feasible and below bounded while being unsolvable;
- both (P) and (D) can be solvable, but with different optimal values, etc.

Importance of strong feasibility is the main reason for our chosen way to represent constraints of a conic program as conic inequality/inequalities augmented by a system of linear equality constraints. In principle, we could write a conic problem (P) without equality constraints, namely, as

$$\min_x \left\{ c^T x : A_i x - b_i \in \mathbf{K}_i, 1 \leq i \leq m, Rx - r \in \mathbf{R}_+^k, r - Rx \in \mathbf{R}_+^k \right\} \quad [k = \dim r]$$

— the possibility we used, to save notation, in LO. Now it would be unwise to treat equality constraints via pairs of opposite inequalities – the resulting problem would definitely be *not* strictly feasible⁴.

Refinement

We can slightly refine the Conic Duality Theorem, extending the “special treatment” from linear equality constraints to *scalar* linear inequalities. Specifically, consider problem (P) and assume that one of the conic constraints in the problem, say, the first one, is just $A_1 x - b_1 \geq 0$, that is, $F_1 = \mathbf{R}^\mu$ with the standard inner product, and \mathbf{K}_1 is the corresponding nonnegative orthant. Thus, our primal problem is

$$\text{Opt}(P) = \min_x \left\{ \langle c, x \rangle_E : \begin{array}{ll} A_1 x - b_1 \geq 0 & (a) \\ A_i x - b_i \in \mathbf{K}_i, 2 \leq i \leq m, & (b) \\ Rx = r & (c) \end{array} \right\} \quad (P)$$

so that the dual (D) is

$$\text{Opt}(D) = \max_{z, \{y_i\}_{i=1}^m} \left\{ \langle r, z \rangle_F + b_1^T y_1 + \sum_{i=2}^m \langle b_i, y_i \rangle_{F_i} : \begin{array}{l} y_1 \geq 0, \\ y_i \in \mathbf{K}_i^*, 2 \leq i \leq m, \\ R^* z + \sum_{i=1}^m A_i^* y_i = c \end{array} \right\} \quad (D)$$

Essentially strict feasibility. Note that the structure of problem (D) is completely similar to the one of (P) – the variables, let them be called ξ , are subject to finitely many *scalar* linear equalities and inequalities and, on the top of it, finitely many conic inequalities $P_i \xi - p_i \in \mathbf{L}_i$, $i \in I$, where \mathbf{L}_i are regular cones in Euclidean spaces. Let us call such a conic problem *essentially strictly feasible*, if it admits a feasible solution $\bar{\xi}$ at which the conic inequalities are satisfied strictly: $P_i \bar{\xi} - p_i \in \text{int } \mathbf{L}_i$, $i \in I$. It turns out that the Conic Duality Theorem 7.1.1 remains valid when one replaces in it “strict feasibility” with “essentially strict feasibility,” which is some progress: a strictly feasible conic problem clearly is essentially strictly feasible, but not necessarily vice versa. Thus, we intend to prove

Theorem 7.1.2 [Refined Conic Duality Theorem] *Consider a primal-dual pair of conic programs (P) , (D) . Then*

- (i) [Weak Duality] *One has $\text{Opt}(D) \leq \text{Opt}(P)$.*
- (ii) [Symmetry] *The duality is symmetric: (D) is a conic program, and the program dual to (D) is (equivalent to) (P) .*
- (iii) [Refined Strong Duality] *If one of the programs (P) , (D) is essentially strictly feasible and bounded, then the other program is solvable, and $\text{Opt}(P) = \text{Opt}(D)$.*

If both the programs are essentially strictly feasible, then both are solvable with equal optimal values.

Note that the Refined Conic Duality Theorem covers the usual Linear Programming Duality Theorem: the latter is the particular case $m = 1$ of the former.

⁴Another way to eliminate equality constraints, which is free of the outlined shortcoming, could be to use the equality constraints to express part of the variables as linear functions of the remaining variables, thus reducing the design dimension of the problem and getting rid of equality constraints.

Proof of Theorem 7.1.2. With the Conic Duality Theorem at our disposal, all we should take care of now is the refined strong duality. In other words, invoking primal-dual symmetry, all we need is to prove that

(!) If (P) is essentially strictly feasible and bounded, then (D) is solvable, and $\text{Opt}(P) = \text{Opt}(D)$.

Thus, assume that (P) is essentially strictly feasible and bounded.

1⁰. Let

$$X = \{x : A_1x \geq b_1, Rx = r\}.$$

This set is nonempty. Let $\Pi = \{x : Rx = r, Sx = s\}$ be the affine span of X . We claim that *Either*

(A) $X = \Pi = \{x : Rx = r, Sx = s\}$, or

(B) $X = \{x : Rx = r, Sx = s, C_1x \geq d_1\}$ with properly selected C_1, d_1 such that there exists $x' \in X$ satisfying $C_1x' > d_1$.

Indeed, assume that (A) is not the case, and let $L = \{x : Rx = 0, Sx = 0\}$ be the linear subspace to which Π is parallel. Let α_i^T , $1 \leq i \leq \mu$, be the rows of A_1 , β_i be the entries in b_1 , and σ_i be the orthogonal projections of α_i onto L , so that

$$L \ni \sigma_i = \alpha_i - R^T u_i - S^T v_i$$

for properly selected vectors u_i, v_i . We clearly have

$$X = \{x : Rx = r, Sx = s, \sigma_i^T x \geq \delta_i := \beta_i - r^T u_i - s^T v_i, 1 \leq i \leq \mu\}$$

Let $I = \{i : \sigma_i \neq 0\}$. For every $i \notin I$, the inequality $[0^T x] = \sigma_i^T x \geq \delta_i$ holds true for some x (namely, for every $x \in X$) and thus is identically true. It follows that

$$X = \{x : Rx = r, Sx = s, C_1x \geq d_1\}, \quad (7.1.5)$$

where the rows of C_1 are the vectors σ_i^T , $i \in I$, and the entries in d_1 are the respective quantities δ_i . Note that $I \neq \emptyset$ since $X \neq \Pi$. To complete the justification of our claim, it remains to note that every point x' from the relative interior of X (this set is nonempty!) satisfies $x' \in \Pi$, $C_1x' > d_1$. Indeed, X contains a set of the form $U(x') = x' + \{h \in L : \|h\|_2 \leq \delta(x')\}$ with some $\delta(x') > 0$; since the relation $C_1x \geq d_1$ should be valid on $U(x')$ and the rows of C_1 are (transposes of) nonzero vectors from L , this implies $C_1x' > d_1$.

2⁰. Consider the case of (B), and let us pass from the original problem (P) to the *equivalent* problem

$$\text{Opt}(P) = \min_x \left\{ \langle c, x \rangle_E : \begin{cases} C_1x - d_1 \geq 0 & (a) \\ A_ix - b_i \in \mathbf{K}_i, i = 2, 3, \dots, m, & (b) \\ \begin{cases} Rx = r \\ Sx = s \end{cases} & (c) \end{cases} \right\} \quad (\bar{P})$$

The equivalence of (P) and (\bar{P}) is an immediate corollary of the fact that the set X of x 's satisfying $(P.a)$ and $(P.c)$ is, by construction, exactly the same as the set of x 's satisfying $(\bar{P}.a)$ and $(\bar{P}.c)$. Our next observation is that (\bar{P}) is strictly feasible. Indeed, let \bar{x} be a feasible solution to (P) such that $A_i\bar{x} - b_i \in \text{int } \mathbf{K}_i$, $i = 2, \dots, m$; existence of such a solution is given by essentially strict feasibility of (P) . Now let $x' \in X$ be such that $C_1x' > d_1$ (we have seen in the previous item that such x' exists). Then for every $\lambda \in (0, 1)$, the point $x_\lambda = (1 - \lambda)\bar{x} + \lambda x'$ belongs to X and thus satisfies $(P.c)$, same as satisfies the strict version $C_1x_\lambda > d_1$ of $(\bar{P}.a)$. For small positive λ x_λ clearly satisfies also the inclusions $A_ix_\lambda - b_i \in \text{int } \mathbf{K}_i$, $i = 2, 3, \dots, m$ and therefore is a strictly feasible solution to (\bar{P}) . Thus, (\bar{P}) is strictly

feasible (and bounded along with (P)), so that by the Conic Duality Theorem the dual to (\bar{P}) – the problem

$$\text{Opt}(\bar{D}) = \max_{z, w, \eta, \{y_i\}_{i=2}^m} \left\{ \begin{array}{l} \langle r, z \rangle_F + s^T w + d_1^T \eta + \sum_{i=2}^m \langle y_i, b_i \rangle_{F_i} : \\ \eta \geq 0 \\ y_i \in \mathbf{K}_i^*, 2 \leq i \leq m \\ R^* z + S^T w + C_1^* \eta + \sum_{i=2}^m A_i^* y_i = c \end{array} \right\}_{(\bar{D})}$$

is solvable with the optimal value $\text{Opt}(P)$. Let $z^*, w^*, \eta^*, y_2^*, \dots, y_m^*$ be an optimal solution to (\bar{D}) . All we need to prove is that this solution can be converted to a feasible solution to (D) with the value of the objective of (D) at this feasible solution at least $\text{Opt}(\bar{D})$ (since we have seen that $\text{Opt}(\bar{D}) = \text{Opt}(P)$, by Weak duality the resulting solution will be optimal for (D) with the value of the objective equal to $\text{Opt}(P)$, which is all we need).

To convert $(z^*, w^*, \eta^*, y_2^*, \dots, y_m^*)$ into a feasible solution to (D) , let us act as follows. To simplify notation, we may assume w.l.o.g. that $w^* \geq 0$. Indeed, we can multiply by (-1) the equations in the system $Sx = s$ which correspond to negative entries in w^* , replacing simultaneously these entries with their magnitudes; in our context, this clearly changes nothing.

Now, the system of linear inequalities and equations

$$C_1 x \geq d_1 \text{ \& } Rx = r \text{ \& } Sx \geq s$$

is satisfied everywhere on the *nonempty* solution set X of the system

$$A_1 x \geq b_1 \text{ \& } Rx = r.$$

Consequently, by Inhomogeneous Farkas Lemma, there exist entrywise nonnegative matrices G, H and matrices U, V of appropriate sizes such that

$$\begin{array}{lll} (a.1) & C_1 & = GA_1 + UR, \\ (a.2) & Gb_1 + Ur & \geq d_1; \\ (b.1) & S & = HA_1 + VR, \\ (b.2) & Hb_1 + Vr & \geq s. \end{array} \quad (7.1.6)$$

Now consider the candidate solution $\bar{z}, \bar{y}_1, \dots, \bar{y}_m$ to (D) as follows:

$$\begin{aligned} \bar{z} &= z^* + U^* \eta^* + V^* w^* \\ \bar{y}_1 &= G^* \eta^* + H^* w^* \\ \bar{y}_i &= y_i^*, i = 2, \dots, m. \end{aligned}$$

This indeed is a feasible solution to (D) ; all we need to verify is that $\bar{y}_1 \geq 0$ (this is true due to $\eta^* \geq 0$, $w^* \geq 0$ and to entrywise nonnegativity of G, H) and that $R^* \bar{z} + \sum_{i=1}^m A_i^* \bar{y}_i = c$. The latter is immediate:

$$\begin{aligned} c &= R^* z^* + S^* w^* + C_1^* \eta^* + \sum_{i=2}^m A_i^* y_i^* = R^* [z^* + U^* \eta^* + V^* w^*] + A_1^* [G^* \eta^* + H^* w^*] + \sum_{i=2}^m A_i^* y_i^* \\ &= R^* \bar{z} + A_1^* \bar{y}_1 + \sum_{i=2}^m A_i^* \bar{y}_i, \end{aligned}$$

where the equalities follow from (a) the fact that $(z^*, w^*, \eta^*, y_2^*, \dots, y_m^*)$ is feasible for (\bar{D}) , (b) (7.1.6.a.1, b.1), and (c) the definition of \bar{z}, \bar{y}_i .

Further, we have

$$\begin{aligned} [\text{Opt}(P) =] \text{Opt}(\bar{D}) &= \langle r, z^* \rangle_F + s^T w^* + d_1^T \eta^* + \sum_{i=2}^m \langle y_i^*, b_i \rangle_{F_i} \\ &\leq \langle r, z^* \rangle_F + [Hb_1 + Vr]^T w^* + [Gb_1 + Ur]^T \eta^* + \sum_{i=2}^m \langle y_i^*, b_i \rangle_{F_i} \\ &= \langle r, z^* + U^* \eta^* + V^* w^* \rangle_F + b_1^T [H^* w^* + G^* \eta^*] + \sum_{i=2}^m \langle y_i^*, b_i \rangle_{F_i} \\ &= \langle r, \bar{z} \rangle_F + \sum_{i=1}^m \langle \bar{y}_i, b_i \rangle_{F_i}, \end{aligned}$$

where the first inequality is due to $w^* \geq 0, \eta^* \geq 0$ and (7.1.6.a.2, b.2), and the last equality is due to the definition of $\bar{z}, \bar{y}_1, \dots, \bar{y}_m$. The resulting inequality, as it was already explained, implies that $\bar{z}, \bar{y}_1, \dots, \bar{y}_m$ form an optimal solution to (D) and that $\text{Opt}(P) = \text{Opt}(D)$, which is all we need.

3⁰. We have verified (!) in the case of (B). In the case of (A) the verification is completely similar, up to straightforward simplifications, with the equivalent reformulation

$$\text{Opt}(P) = \min_x \left\{ \langle c, x \rangle_E : \begin{cases} A_i x - b_i \in \mathbf{K}_i, i = 2, 3, \dots, m, & (b) \\ Rx = r & \\ Sx = s & (c) \end{cases} \right\} \quad (\tilde{P})$$

of (P) in the role of (\bar{P}) and the relations (7.1.6.b) in the role of (7.1.6.a,b). The detailed proof is left to the reader.

Another option is to note that in the case of (A) we still have

$$X = \{x : Rx = r, Sx = s, C_1 x \geq d_1\}$$

with essentially strictly feasible system of constraints (i.e., $C_1 x > d_1$ for some $x \in X$); indeed, it suffices to set $C_1 = [0, \dots, 0]$, $d_1 = -1$. This allows to reduce the case of (A) to the case of (B).⁵ \square

7.1.4 Consequences of Conic Duality Theorem

Optimality Conditions in Conic Programming

Optimality conditions in Conic Programming are given by the following statement:

Theorem 7.1.3 *Consider a primal-dual pair (P) , (D) of conic programs, and let both programs be essentially strictly feasible. A pair $(x, \xi \equiv [z; y_1; \dots; y_m])$ of feasible solutions to (P) and (D) is comprised of optimal solutions to the respective programs iff*

(i) [Zero duality gap] *One has*

$$\begin{aligned} \text{DualityGap}(x; \xi) &:= \langle c, x \rangle_E - [\langle z, r \rangle_F + \sum_i \langle b_i, y_i \rangle_{F_i}] \\ &= 0, \end{aligned}$$

same as iff

(ii) [Complementary slackness]

$$\forall i : \langle y_i, A_i x_i - b_i \rangle_{F_i} = 0.$$

Proof:

By Refined Conic Duality Theorem, we are in the situation when $\text{Opt}(P) = \text{Opt}(D)$. Therefore

$$\begin{aligned} \text{DualityGap}(x; \xi) &= \underbrace{[\langle c, x \rangle_E - \text{Opt}(P)]}_a \\ &\quad + \underbrace{\left[\text{Opt}(D) - \left[\langle z, b \rangle_F + \sum_i \langle b_i, y_i \rangle_{F_i} \right] \right]}_b \end{aligned}$$

⁵The second option follows the old joke: Given an egg, an empty pan, a stove and a source of water, you need to boil the egg. How should you act? – Well, you pour water into the pan, put the egg there and place the pan on the stove to boil the water. Now you need to solve a close problem: all as before, except that now the pan contains the water from the very beginning. How should you act? – You pour the water out of the pan and reduce the problem to the previous one...

Since x and ξ are feasible for the respective programs, the duality gap is nonnegative and it can vanish iff $a = b = 0$, that is, iff x and ξ are optimal solutions to the respective programs, as claimed in (i). To prove (ii), note that since x is feasible, we have

$$Rx = r, A_i x - b_i \in \mathbf{K}_i, c = A^* z + \sum_i A_i^* y_i, y_i \in \mathbf{K}_i^*,$$

whence

$$\begin{aligned} \text{DualityGap}(x; \xi) &= \langle c, x \rangle_E - [\langle z, r \rangle_F + \sum_i \langle b_i, y_i \rangle_{F_i}] \\ &= \langle R^* z + \sum_i A_i^* y_i, x \rangle_E - [\langle z, r \rangle_F + \sum_i \langle b_i, y_i \rangle_{F_i}] \\ &= \underbrace{\langle z, Rx - r \rangle_F}_{=0} + \sum_i \underbrace{\langle y_i, A_i x - b_i \rangle_{F_i}}_{\geq 0}, \end{aligned}$$

where the nonnegativity of the terms in the last \sum_i follows from $y_i \in \mathbf{K}_i^*, A_i x - b_i \in \mathbf{K}_i$. We see that the duality gap, as evaluated at a pair of primal-dual feasible solutions, vanishes iff the complementary slackness holds true, and thus (ii) is readily given by (i). \square

A Surrogate of GTA

The following statement is a slightly weakened forms of the Inhomogeneous Farkas Lemma (which is equivalent to GTA):

Proposition 7.1.1 [Conic Inhomogeneous Farkas Lemma] *Let \mathbf{K} be a regular cone. A scalar linear inequality*

$$p^T x \geq q \tag{*}$$

is a consequence of essentially strictly feasible system

$$Ax - b \in \mathbf{K}, Rx = r \tag{!}$$

comprised of a conic inequality and a system of linear equations⁶ iff () is “linear consequence” of (!), i.e., iff there exists λ, μ such that*

$$\lambda \in \mathbf{K}^*, A^* \lambda + R^* \mu = p, \langle b, \lambda \rangle + \langle r, \mu \rangle \geq q. \tag{7.1.7}$$

Proof. Let (*) be a consequence of (!). Then the (essentially strictly feasible!) conic program

$$\min_x \{p^T x : Ax - b \in \mathbf{K}, Rx = r\}$$

is below bounded with optimal value $\geq q$. Applying the Refined Conic Duality Theorem, the dual program has a feasible solution with the value of the dual objective $\geq q$, which is nothing but the solvability of (7.1.7) (look at the dual!). Vice versa, if λ, μ solve (7.1.7) and x solves (!), then

$$0 \leq \langle \lambda, Ax - b \rangle + \langle \mu, Rx - r \rangle = [A^* \lambda + R^* \mu]^T x - \langle b, \lambda \rangle - \langle r, \mu \rangle = p^T x - \langle b, \lambda \rangle - \langle r, \mu \rangle \leq p^T x - q,$$

so that (*) indeed is a consequence of (!); note that to get the latter conclusion, no assumption of essentially strict feasibility (and even feasibility) of (!) is needed. \square

⁶Essentially strict feasibility of (!) is defined completely similarly to essentially strict feasibility of a conic problem; it means that \mathbf{K} is the direct product of a nonnegative orthant (perhaps of dimension 0) and a regular cone \mathbf{K}' , and (!) has a feasible solution \bar{x} with the \mathbf{K}' -component belonging to the interior of \mathbf{K}' .

*Certificates of robust solvability status

In LO, we know complete certification schemes for the basic components of the “solvability status” of an LO program, that is, we know how to certify that the program is feasible/infeasible, feasible and bounded or feasible and unbounded, same as we know that a program is solvable iff it is feasible and bounded; all these certification schemes stem from LO Duality Theorem, see section 3.1.3. In the conic case, we have a slightly weaker version of the Duality Theorem, and a result, the question of what are the complete certification schemes for feasibility, boundedness and solvability becomes much more difficult. It, however, admits simple answers when we ask about *robust presence* of a particular property rather than of its “plain” presence. Specifically, consider a conic problem in the single-cone form:

$$\min_x \{c^T x : Ax - b \in \mathbf{K}, Rx = r\} \quad (\mathcal{P})$$

along with its dual problem

$$\max_{y,z} \{\langle b, y \rangle + \langle r, z \rangle : y \in \mathbf{K}^*, A^*y + R^*z = c\} \quad (\mathcal{D})$$

and assume that the systems of linear equality constraints in (\mathcal{P}) and in (\mathcal{D}) are feasible⁷. Now imagine that we fix once for ever part of the data, namely, R, r, A, \mathbf{K} , but allow to perturb slightly the objective c , keeping it all the time in the image C of the linear map $(y, z) \mapsto A^*y + R^*z$, same as allow to perturb slightly the primal right hand side vector b . It may happen that arbitrarily small perturbations allow to change a particular component of the solvability status of (\mathcal{P}) , say, convert a feasible program (\mathcal{P}) into an infeasible one; in this case, we say that (\mathcal{P}) possesses the property in a *non-robust* fashion. It may happen also that there exist $\delta > 0$ such that whenever b is replaced with b' such that $\|b - b'\| \leq \epsilon$, and c is replaced with $c' \in C$ such that $\|c - c'\| \leq \epsilon$, the property in question remains intact. In this case, we say that (\mathcal{P}) possess the property in a *robust* fashion. Specifically, we say that program (\mathcal{P}) is

- *robustly feasible*, if it is feasible and remains to be so when we replace b with a b' which is close enough to b (specifically, “if there exists $\epsilon > 0$ such that whenever $\|b' - b\| \leq \epsilon \dots$ ”);
- *robustly infeasible*, if it is infeasible and remains to be so when we replace b with a b' close enough to b ;
- *robustly bounded*, if it is robustly feasible and bounded, and remains bounded when we replace c with $c' \in C$ close enough to c ;
- *robustly unbounded*, if it is robustly feasible and unbounded, and remains unbounded when we replace c with $c' \in C$ close enough to c ;
- *robustly solvable*, if it is solvable and remains so when we replace b and c with $b', c' \in C$ close enough to b, c , respectively;
- *robustly unsolvable*, if it is unsolvable and remains so when we replace b and c with $b', c' \in C$ close enough to b, c , respectively.

⁷This assumption, which can be easily checked by elementary Linear Algebra tools, is quite natural: when the system of linear inequalities $RX = r$ in (\mathcal{P}) is infeasible, (\mathcal{P}) is infeasible. When the system of linear inequalities $A^*y + R^*z = c$ in (\mathcal{D}) is unsolvable, c has a negative inner product with certain vector h such that $Ah = 0$ and $Rh = 0$ (“kernel of a linear mapping is the orthogonal complement to the image space of the conjugate mapping”), meaning that (\mathcal{P}) is either infeasible, or unbounded (why?). In all these cases (\mathcal{P}) is “bad.”

In the sequel, we refer to the problem (\mathcal{P}) with vectors b, c replaced with b', c' as to $(\mathcal{P}[b', c'])$, so that (\mathcal{P}) is the same as $(\mathcal{P}[b, c])$.

Warning! *In the above pairs of properties, one member is not the negation of the other member.* E.g., a program which is not robustly feasible, not necessary is robustly infeasible! In fact, it can be even feasible, but “at the border of feasibility:” – by appropriate arbitrarily small perturbation in b we can make it infeasible. This is like colors in gray scale: an object can be black, it can be white, and it can be gray – neither black nor white.

Why should we bother on robustness? The point is that if a conic program (\mathcal{P}) possesses certain solvability-related feature – say, feasibility – in a non-robust fashion, then, by definition, we can change this feature by appropriate *arbitrary small* perturbation of the part of the data, namely, b and c . In contrast to this, the property to possess *robustly* certain feature “is itself robust” – it is preserved by small enough perturbations in b and c . Theoretically speaking, in LO with rational data we can use, e.g., Khachiyan’s algorithm to recover in CT-polynomial time the “true” solvability status of an LO instance, along with building the corresponding certificates. Similar possibility exists in LO with real data in the Real Arithmetic model of computations — it suffices to solve the LO program in question by the Simplex method. Note, however, that the resulting procedure is *not* ReACM-polynomial. In “non-polyhedral” conic optimization, even in the Real Arithmetics model of computations, there is no theoretical possibility to recover in finite time the true solvability status of an instance (or at least we do not know how to do it). As about real life finite precision computations, the situation is even worse. When solving a problem with non-robust (or even “robust, but poorly so”) solvability status, rounding errors can lead to completely wrong conclusions on this status, and this happens in the LO case as well⁸.

Motivated by the above discussion, we are about to understand what robustness amounts to and how to it can be certified.

A. Robust feasibility. We claim that (\mathcal{P}) is *robust feasible* iff (\mathcal{P}) is *strictly feasible*. As a result, *to certify robust feasibility, it suffices to point out a vector x such that $Ax - b \in \text{int } \mathbf{K}$, and this certification scheme is complete.*

The second claim is an immediate corollary of the first one, and the latter can be certified as follows. If (\mathcal{P}) is strictly feasible, this program clearly is robust feasible (why?). Now assume that the program is not strictly feasible, and let us prove that then it is not robust feasible as well. To this end, let $\Delta \in \text{int } \mathbf{K}$; given $t > 0$, consider the program $(\mathcal{P}[b', c])$ with $b' = b - t\Delta$. We claim that this problem is infeasible. Indeed, assuming that \bar{x} is a feasible solution to $(\mathcal{P}[b', c])$, we would get $R\bar{x} = r$ and $A\bar{x} - b = A\bar{x} - b' + t\Delta$; the latter vector clearly belongs to $\text{int } \mathbf{K}$ (since as the sum of the vector $A\bar{x} - b'$ from \mathbf{K} and the vector $t\Delta \in \text{int } \mathbf{K}$), meaning that (\mathcal{P}) is strictly feasible, which was assumed not to be the case. When t is close to 0, $t\Delta$ is small, and we see that by arbitrarily small perturbations of (\mathcal{P}) we can make the problem infeasible, so that (\mathcal{P}) is not robustly feasible, as claimed. \square

⁸Everybody with even small experience of solving LO’s with commercial software knows a lot of examples when definitely solvable problems were claimed infeasible or unbounded; I remember my shock when a quite respectable code managed to solve my problem to optimality before I removed one of the constraints and claimed it infeasible after the constraint was removed. Good LO solvers at least report that in course of computations, some numerical difficulties were met, so that the results should be accepted “with a grain of salt;” not so good solvers do not care to report on difficulties...

B. Robust infeasibility. We claim that (\mathcal{P}) is robustly infeasible iff the constraints of the problem can be led to a contradiction by linear aggregation, that is, iff there exists $[y; z]$ such that

$$y \in \mathbf{K}^*, A^*y + R^*z = 0, \langle b, y \rangle + \langle r, z \rangle > 0. \quad (7.1.8)$$

As a result, to certify robust infeasibility of (\mathcal{P}) , it suffices to point out a solution $[y; z]$ to (7.1.8), and this certification scheme is complete.

Here again it suffices to prove the first claim only. Assume, first, that (7.1.8) has a solution $[y; z]$, and let us prove that (\mathcal{P}) is robustly infeasible. Indeed, since $\langle b, y \rangle + \langle z, r \rangle > 0$, there exists a small enough centered at b ball B of positive radius such that $\langle b', y \rangle + \langle z, r \rangle > 0$ whenever $b' \in B$. Let us prove that every problem $(\mathcal{P}[b', c])$ $b' \in B$ is infeasible (this would mean that (\mathcal{P}) is robustly infeasible, as desired). Indeed, assuming that x is feasible for $(\mathcal{P}[b', c])$ and $b' \in B$, we would get $\langle y, Ax - b' \rangle \geq 0$ (since $y \in \mathbf{K}^*$ and $Ax - b' \in \mathbf{K}$) and $\langle z, Rx - r \rangle = 0$; summing up these inequalities, we get $\langle A^*y + R^*z, x \rangle - \langle y, b' \rangle - \langle z, r \rangle \geq 0$, that is, $-\langle y, b' \rangle - \langle z, r \rangle \geq 0$, which is impossible due to $b' \in B$. Thus, $(\mathcal{P}[b', c])$ is infeasible when $b' \in B$, as claimed.

Now let us verify that if (\mathcal{P}) is robust infeasible, then (7.1.8) is solvable. To this end, let us choose $\Delta \in \text{int } \mathbf{K}$, and consider the conic program

$$\min_{t, x} \{t : Ax + t\Delta - b \in \mathbf{K}, Rx = r\}. \quad (!)$$

We claim that this problem is feasible with strictly positive optimal value. Strict feasibility is evident: take a whatever x satisfying $Rx = r$; then for all large enough values of t we have $t^{-1}[Ax - b] + \Delta \in \text{int } \mathbf{K}$ due to $\Delta \in \text{int } \mathbf{K}$, whence $Ax - b + t\Delta \in \text{int } \mathbf{K}$ as well. The fact that the optimal value is positive stems from the fact that otherwise (!) would have feasible solutions with t arbitrarily close to 0, that is, program $(\mathcal{P}[b', c])$ with $b' = b - t\Delta$, would be feasible for all close to 0 values of t , which contradicts the robust infeasibility of (\mathcal{P}) . Since (!) is strictly feasible with positive value of the objective, by Conic Duality Theorem the program dual to (!), that is, the program

$$\max_{y, z} \{\langle b, y \rangle + \langle r, z \rangle : y \in \mathbf{K}^*, A^*y + R^*z = 0, \langle y, \Delta \rangle = 1\}$$

has a feasible solution with positive values of the objective, meaning that (7.1.8) is solvable. \square

C. Robust boundedness. We claim that (\mathcal{P}) is robustly bounded iff either (\mathcal{P}) is robustly infeasible, or (\mathcal{D}) is strictly feasible. As a result, in order to certify robust boundedness of (\mathcal{P}) , it suffices either to certify robust infeasibility of (\mathcal{P}) (which we already know how to do), or to point out a strictly feasible solution to (\mathcal{D}) , and this certification scheme is complete.

We need to prove the first claim only. In one direction: Assume that (\mathcal{P}) is robustly bounded. We should prove that if, in addition, (\mathcal{P}) is not robustly infeasible, then (\mathcal{D}) is strictly feasible. We should, therefore, lead to a contradiction the assumption that (\mathcal{P}) is robustly bounded, (\mathcal{P}) is not robustly infeasible, and (\mathcal{D}) is not strictly feasible. Assume that all these properties take place. Since (\mathcal{P}) is robustly bounded, there exists $\epsilon > 0$ such that whenever $\|b' - b\| \leq \epsilon$ and $c' \in C$, $\|c' - c\| \leq \epsilon$, the problem $(\mathcal{P}[b', c'])$ is bounded. Since (\mathcal{P}) is not robustly infeasible, we can find b'' , $\|b'' - b\| \leq \epsilon/2$, such that $(\mathcal{P}[b'', c])$ is feasible; therefore, setting $b' = b'' - \Delta$ with small in norm $\Delta \in \text{int } \mathbf{K}$, we get a strictly feasible problem $(\mathcal{P}[b', c])$ and ensure that $\|b - b'\| \leq \epsilon$. Now, the dual to $(\mathcal{P}[b', c])$ is the problem $(\mathcal{D}[b', p'])$ obtained from (\mathcal{D}) by replacing

b with b' and c with c' . Since $(\mathcal{P}[b', c])$ is strictly feasible and bounded, its dual $(\mathcal{D}[b', c])$ is solvable and thus feasible. But the feasible set of $(\mathcal{D}[b', c])$ is the same as the feasible set of (\mathcal{D}) , so that the latter is nonempty. Now let $[y; z]$ be a feasible solution to (\mathcal{D}) , and let $\Delta \in \text{int } \mathbf{K}^*$. Setting $c(t) = A^*[y - t\Delta] + R^*z$, we see that $c(t) \in C$, $c(0) = c$ and the program $(\mathcal{D}[b, c(t)])$ is infeasible for every $t > 0$ (since if $[\tilde{y}; \tilde{z}]$ were a feasible solution to the latter program, $[\tilde{y} + t\Delta; \tilde{z}]$ would be a strictly feasible solution to (\mathcal{D}) , and we are in the case when (\mathcal{D}) is not strictly feasible). Choosing small enough $t > 0$ and setting $c' = c(t)$, we ensure that $\|c' - c\| \leq \epsilon$ and the problem $(\mathcal{D}[b, c'])$ is infeasible, meaning that the problem $(\mathcal{D}[b', c'])$ also is infeasible. We arrive at a contradiction: since $\|b' - b\| \leq \epsilon$, $\|c' - c\| \leq \epsilon$ and $c' \in C$, program $(\mathcal{P}[b', c'])$ should be either infeasible, or feasible and bounded. The former option is impossible, since the feasible set of the program is the same as for $(\mathcal{P}[b', c])$, that is, the program is even strictly feasible. We conclude that $(\mathcal{P}[b', c'])$ is strictly feasible and bounded, whence, by Conic Duality Theorem, $(\mathcal{D}[b', c'])$ is feasible, which by construction of c' is not the case. We have arrived at the desired contradiction, thus proving that *if* (\mathcal{P}) is robustly bounded, *then* the program either is robustly infeasible, or (\mathcal{D}) is strictly feasible.

In the opposite direction: We should prove that *if* (\mathcal{P}) is either robustly infeasible, or (\mathcal{D}) is strictly feasible, *then* (\mathcal{P}) is robustly bounded. If (\mathcal{P}) is robustly infeasible, then of course it is robustly bounded. Now let (\mathcal{D}) be strictly feasible, and let $[\bar{y}; \bar{z}]$ be a strictly feasible solution to the problem, so that a ball Y of a positive radius r centered at \bar{y} is contained in \mathbf{K}^* . By elementary linear algebra, we can find *continuous in* $c' \in C$ functions $y(c')$ and $z(c')$ such that $y(c) = \bar{y}$ and $A^*y(c') + R^*z(c') = c'$ for all $c' \in C$. In particular, we can find $\epsilon > 0$ such that whenever $c' \in C$ and $\|c' - c\| \leq \epsilon$, we have $\|y(c') - \bar{y}\| \leq r$, meaning that $y(c') \in \mathbf{K}^*$ and thus $[y(c'); z'(c')]$ is a feasible solution to $(\mathcal{D}[b', c'])$ for all b' . By Weak Duality it follows that $(\mathcal{P}[b', c'])$ is either infeasible, or bounded for every b' and every $c' \in C$ such that $\|c' - c\| \leq \epsilon$, meaning that (\mathcal{P}) is robustly bounded. \square

B. Robust unboundedness. We claim that (\mathcal{P}) is *robustly unbounded* iff (\mathcal{P}) is *robustly feasible* and there exists h such that

$$Ah \in \mathbf{K}, Rh = 0, c^T h < 0. \quad (7.1.9)$$

Consequently, to certify robust unboundedness of (\mathcal{P}) , it suffices to point out a certificate of robust feasibility (that is, a strictly feasible solution to (\mathcal{P}) , see above) and a vector h satisfying (7.1.9), and this certification scheme is complete.

As always, it suffices to prove the first claim. In one direction: assume that (\mathcal{P}') is robustly feasible and a direction h satisfying (7.1.9) does exist. Then there exists a ball B of positive radius centered at c such that $[c']^T h < 0$ for all $c' \in B$. It follows that there exists $\epsilon > 0$ such that whenever $\|b' - b\| \leq \epsilon$ and $\|c' - c\| \leq \epsilon$, the problem $(\mathcal{P}[b', c'])$ is feasible and $[c']^T h < 0$. With b', c' as above, h clearly is a recessive direction of the feasible set of $(\mathcal{P}[b', c'])$, and along this direction the objective of $(\mathcal{P}[b', c'])$ strictly decreases, meaning that $(\mathcal{P}[b', c'])$ is unbounded.

Now assume that (\mathcal{P}) is robustly unbounded, and let us verify that then (\mathcal{P}) is robustly feasible (this is evident) and (7.1.9) has a solution. It may happen that the linear mapping $x \mapsto \mathcal{A}x = \begin{bmatrix} Ax \\ Rx \end{bmatrix}$ has a nontrivial kernel L . Note that in this case the image C of the mapping $[y; z] \mapsto A^*y + R^*z$ is exactly L^\perp , so that restricting x and h to reside in $C = L^\perp$ does not affect neither the robust unboundedness of (\mathcal{P}) , nor the solvability status of (7.1.9). Thus,

we can assume w.l.o.g. that $C = \mathbf{R}^n$ is the entire space of x 's, and the linear mapping \mathcal{A} has a trivial kernel. Now let us prove the existence of h satisfying (7.1.9).

Let $H = \{h \in \mathbf{R}^n : Ah \in \mathbf{K}, Rh = 0\}$. H clearly is a closed convex cone in \mathbf{R}^n . We claim that this cone is pointed. Indeed, if h is such that $\pm h \in H$, then $Rh = 0$ and $\pm Ah \in \mathbf{K}$; since \mathbf{K} is pointed, it follows that $Ah = 0$. Thus, $Ah = 0$ and $Rh = 0$, whence $h = 0$ (recall that we are in the situation when the mapping $x \mapsto (Ax, Rx)$ has the trivial kernel). Now let us use the following simple and important

Lemma 7.1.1 *If M is a closed pointed cone in \mathbf{R}^n , then there exists $f \in H^*$ and a constant $\theta > 0$ such $\|h\|_2 \leq \theta f^T h$ for all $h \in M$. Specifically, one can take as f any vector from the nonempty set $\text{int } H^*$.*

Proof of Lemma. Since M is a closed pointed cone, its dual cone M^* has a nonempty interior. Let $f \in \text{int } M^*$, so that there exists r such that $f + e \in M^*$ whenever $\|e\|_2 \leq r$. It follows that when $h \in M$, we have $0 \leq \min_{e: \|e\|_2 \leq r} [f + e]^T h = f^T h - r\|h\|_2$, so that $r\|h\|_2 \leq f^T h$ for all $h \in M$; it remains to take $\theta = r^{-1}$. \square

Now we are ready to prove that (7.1.9) has a solution. Applying Lemma to the closed pointed cone H , we see that there exists a vector $f \in \mathbf{R}^n$ and $\theta > 0$ satisfying $\theta f^T h \|h\|_2$ for all $h \in H$. Since (\mathcal{P}) is robustly unbounded and we are in the situation $C = \mathbf{R}^n$, there exists $\epsilon > 0$ such that with $c' = c + \epsilon f$, the program $(\mathcal{P}[b, c'])$ is unbounded, that is, there exists a sequence $\{h_t\}_{t=1}^\infty$ of feasible solutions to this problem such that $[c']^T h_t \rightarrow -\infty$ as $t \rightarrow \infty$. This relation is possible only if $\rho_t = \|h_t\| \rightarrow \infty$ as $t \rightarrow \infty$. Now let $e_t = \rho_t^{-1} h_t$. Passing to a subsequence $t_i \rightarrow \infty$, $i \rightarrow \infty$ we can assume that the unit vectors e_{t_i} converge, as $i \rightarrow \infty$, to a unit vector e . We have

$$Re_t = \rho_t^{-1} Rh_t = \rho^{-1} r \rightarrow 0, t \rightarrow \infty \Rightarrow Re = 0$$

and

$$Ae_t - \rho_{t-1} b = \rho_t^{-1} [Ah_t - b] \in \mathbf{K},$$

and since \mathbf{K} is closed and $\rho_t^{-1} b \rightarrow 0$, $t \rightarrow \infty$, we see that $Ae \in \mathbf{K}$. The bottom line is that the unit vector e belongs to H . Finally, we have $[c']^T h_t \rightarrow -\infty$ as $t \rightarrow \infty$, whence $[c']^T e = \lim_{i \rightarrow \infty} \rho_{t_i}^{-1} [c']^T h_{t_i} \leq 0$. Recalling what c' is, we see that $c^T e + \epsilon f^T e \leq 0$, and since $e \in H$, we have $\theta f^T e \geq \|e\|_2 = 1$, that is, $\epsilon f^T e \geq \epsilon \theta^{-1}$. The bottom line is that $c^T e + \epsilon \theta^{-1} \leq 0$, whence $c^T e < 0$. Since $e \in H$, (7.1.9) holds true with $e = h$. \square

E. Robust solvability. We claim that (\mathcal{P}) is robustly solvable iff both (\mathcal{P}) and (\mathcal{D}) are strictly feasible. As a result to certify robust solvability of (\mathcal{P}) , it suffices to point out strictly feasible solutions to (\mathcal{P}) and to (\mathcal{D}) , and this certification scheme is complete.

Indeed, assume that (\mathcal{P}) is robustly solvable. Then (\mathcal{P}) clearly is robustly feasible and robustly bounded. The latter fact, in view of item C, implies that (\mathcal{D}) is strictly feasible, while strict feasibility of P' , by item A, implies that (\mathcal{P}) is strictly feasible. Thus, if (\mathcal{P}) is robustly solvable, both (\mathcal{P}) and (\mathcal{D}) are strictly feasible.

To prove the inverse statement, assume that (\mathcal{P}) and (\mathcal{D}) are strictly feasible, and let \bar{y}, \bar{z} be a strictly feasible solution to (\mathcal{D}) . By the argument from item C, we can find continuous functions $y(c')$, $z(c')$ of $c' \in C$ and a neighborhood U of c in C such that for all $c' \in U$ the pair

$y(c'), z(c')$ is a strictly feasible solution to $(\mathcal{D}([b, c']))$, and thus for $(\mathcal{D}[b', c'])$ for all b' . Besides this, by item A $(\mathcal{P}[b', c])$ is feasible for all b' close enough to b , meaning that for these b' the program $(\mathcal{P}[b', c'])$ is feasible for all c' . The bottom line is that for all b' close enough to b and all $c' \in C$ close enough to c problem $(\mathcal{P}[b', c'])$ is feasible (and thus $(\mathcal{D}[b', c'])$ is bounded by Weak duality), and $(\mathcal{D}[b', c'])$ is strictly feasible. Since $(d'[b', c'])$ is strictly feasible and bounded for indicated b', c' , $(\mathcal{P}[b', c'])$ is solvable (Conic Duality Theorem). Thus, $(\mathcal{P}[b', c'])$ is solvable for all b' and $c' \in C$ close enough to b, c , that is, (\mathcal{P}) is robustly solvable. \square

Remark: It should be added that (\mathcal{P}) is robustly solvable iff (\mathcal{P}) is robustly feasible and robustly bounded. Indeed, robustly solvable program clearly is robustly feasible and robustly bounded. To see that inverse also is true, note that if (\mathcal{P}) is robustly feasible, then (\mathcal{P}) is strictly feasible by A and (\mathcal{D}) is strictly feasible by C, whence (\mathcal{P}) is robustly solvable by F.

Remark: From the definitions of robustness it follows that, say, the property to be, say, robust feasible itself is “robust:” if (\mathcal{P}) possesses this property, so are all problems obtained from (\mathcal{P}) by small enough perturbations of b and c , and similarly for all other properties we have considered. Sometimes we can say more. For example, assume that C is the entire x -space (that is, that the mapping $(y, z) \mapsto A^*y + R^*z$ is an onto mapping, or, equivalently, the mapping $x \mapsto (Ax, Rx)$ is with trivial kernel. Then robust solvability of (P) is preserved by small enough perturbations of *all* the data, including A and R (why?).

F. Robust insolvability. We claim that (\mathcal{P}) is robustly unsolvable iff the program is either robustly infeasible, or there exists h satisfying (7.1.9), or both. Since we know how to certify robust infeasibility, this claim yields a complete certification scheme for robust insolvability.

Let us prove our claim. In one direction this is easy: when (\mathcal{P}) is robustly infeasible, then of course (\mathcal{P}) is robustly unsolvable. If there exists h satisfying (7.1.9), then (\mathcal{P}) is robustly unsolvable as well. Indeed, looking at (7.1.9), we see that h satisfying (7.1.9) satisfies also

$$Ah \in \mathbf{K}, Rh = 0, [c']^T h < 0 \quad (*)$$

for all $c' \in V$, where V is a small enough neighborhood of c in C . Now let us prove that $(\mathcal{P}[b', c'])$ is unsolvable, specifically, is either infeasible, or unbounded, for all b' and all $c' \in V$ (and thus (\mathcal{P}) is robustly unsolvable). Indeed, when $(\mathcal{P}[b', c'])$, $c' \in V$, is feasible, h from $(*)$ clearly is a recessive direction of the feasible set of the program such that the objective of the program strictly decreases along this ray, meaning that the program is unbounded.

Now assume that (\mathcal{P}) is robustly unsolvable, and let us prove that the program is either robust infeasible, or (7.1.9) takes place. It suffices to verify that if (\mathcal{P}) is robustly unsolvable and is *not* robustly feasible, then (\mathcal{P}) is robustly unbounded. Thus, let (\mathcal{P}) be robustly unsolvable and not robustly infeasible. Since (\mathcal{P}) is robustly unsolvable, there exists $\epsilon > 0$ such that whenever $b' \in U = \{b' : \|b - b'\| < \epsilon\}$ and $c' \in V = \{c' \in C : \|c' - c\| < \epsilon\}$, the program $(\mathcal{P}[b', c'])$ is unsolvable. Since (\mathcal{P}) is not robustly infeasible, there exists \bar{b} , $\|\bar{b} - b\| \leq \epsilon/2$, such that $(\mathcal{P}[\bar{b}, c'])$ is feasible for all c' . Setting $\tilde{b} = \bar{b} - \Delta$, where $\Delta \in \text{int } \mathbf{K}$ is of norm $\leq \epsilon/3$, we ensure that $\tilde{b} \in U$ and $(\mathcal{P}[\tilde{b}, c'])$ is strictly feasible. We claim that the program $(\mathcal{P}') = (\mathcal{P}[\tilde{b}, c])$ is robustly unbounded. Indeed, since $(\mathcal{P}[\tilde{b}, c])$ is strictly feasible, there exists a neighborhood $W \subset U$ of \tilde{b} such that all programs $(\mathcal{P}[b', c'])$ with $b' \in W$ are strictly feasible. Assuming that $(\mathcal{P}[\tilde{b}, c])$ is not robustly unbounded, we can find $b' \in W$ and $c' \in V$ such that $(\mathcal{P}[b', c'])$ is bounded; since the latter program is strictly feasible due to $b' \in W$, the problem $(\mathcal{D}[b', c'])$ is solvable and thus feasible. If y, z is a feasible solution to $(\mathcal{D}[b', c'])$, then, for every $\Delta \in \text{int } \mathbf{K}^*$, the

pair $y_\Delta = y + \Delta, z$ is a strictly feasible solution to $(\mathcal{D}[b', c_\Delta])$ with $c_\Delta = c' + A^*\Delta$. Choosing $\Delta \in \mathbf{K}^*$ to have a small enough norm, we can ensure that $x'' = x_\Delta \in V$. Thus, $b' \in U, c'' \in V$, problem $(\mathcal{P}[b', c''])$ is feasible, and problem $(\mathcal{D}[b', c''])$ is strictly feasible. By Weak duality, the latter program is not only strictly feasible, but also bounded, which, by Conic Duality Theorem, implies that $(\mathcal{P}[b', c''])$ is solvable, which contradicts the origin of $U \ni b'$ and $V \ni c''$. This contradiction proves that program $(\mathcal{P}[\tilde{b}, c])$ is robustly unbounded. Invoking item D, it follows that either $(\mathcal{P}[\tilde{b}, c])$ is robust infeasible, or there exists an h satisfying (7.1.9). By choice of \tilde{b} , the first option is impossible – problem $(\mathcal{P}[\tilde{b}, c])$ is feasible by construction. We conclude that (7.1.9) has a solution. \square

How “rare” are primal-dual strictly feasible programs? Here we intend to demonstrate that strict primal-dual feasibility (or, which is the same by E, robust solvability) is not too rare commodity: whenever problem (\mathcal{P}) is feasible and bounded, properly chosen arbitrarily small perturbations of b and c make it strictly primal-dual feasible. Specifically,

Proposition 7.1.2 *Let (\mathcal{P}) be feasible and bounded. Whenever $\Delta b \in \text{int } \mathbf{K}$ and $\Delta y \in \text{int } \mathbf{K}^*$, the problem $(\mathcal{P}[b - \Delta b, c + A^*\Delta y])$ is strictly primal-dual feasible.*

Proof. Let $\bar{b} = b - \Delta b$ and $\bar{x} = x + A^*\Delta y$. Every feasible solution to (\mathcal{P}) clearly is a strictly feasible solution to $(\mathcal{P}[\bar{b}, c'])$ for all c' , so that $(\mathcal{P}[\bar{b}, c'])$ is strictly feasible for all c' (recall that (\mathcal{P}) is feasible). We claim that the problem $(\mathcal{P}[\bar{b}, c])$ cannot be robustly unbounded. Indeed, assume that $(\mathcal{P}[\bar{b}, c])$ is robustly unbounded. Then, by item D, (7.1.9) has a solution h . But such an h is a recessive direction of the (nonempty!) feasible domain of (\mathcal{P}) , and along this direction the objective of (\mathcal{P}) strictly decreases, meaning that (\mathcal{P}) is unbounded, which in fact is not the case. Thus, $(\mathcal{P}[\bar{b}, c])$ is not robustly unbounded. Further, $c \in C$. indeed, otherwise, by Linear Algebra, there would exist h such that $Ah = 0, Rh = 0$ and $c^T h < 0$, which, as we just have seen, is impossible. The system of linear equations $A^*y + B^*r = d$ is solvable for all $d \in C$; by Linear Algebra, it admits a linear in $d \in C$ solution $(Y(d), R(d))$. Now let $r > 0$ be such that $\Delta y - e \in \text{int } \mathbf{K}^*$ whenever $\|e\| \leq r$. Recalling that $(\mathcal{P}[\bar{b}, c])$ is strictly feasible and $y(d)$ is linear, there exists $\epsilon > 0$ such that $(\mathcal{P}[b', c])$ is strictly feasible whenever $\|b' - \bar{b}\| \leq \epsilon$ and $\|Y(d)\| \leq r$ whenever $d \in C$ and $\|d\|_2 \leq \epsilon$. Let us prove that Since $(\mathcal{P}[\bar{b}, c])$ is not robustly unbounded, there exist $b', \|b' - \bar{b}\| \leq \epsilon$, and $c' \in C$ with $\|c' - c\|_2 \leq \epsilon$ such that the program $(\mathcal{P}[b', c'])$ is not unbounded; since this program is strictly feasible, it should be bounded which, by Conic Duality Theorem, implies that $(\mathcal{D}[b', c'])$ is feasible. Thus, there exist \bar{y} and \bar{r} satisfying

$$\bar{y} \in \mathbf{K}^*, A^*\bar{y} + R^*\bar{z} = c'.$$

Now let us set

$$y^+ = \bar{y} + \Delta y + Y(c - c'), z^+ = \bar{z} + Z(c - c').$$

Observe that $\|Y(c - c')\| \leq r$ due to $\|c - c'\| \leq \epsilon$, whence $\Delta y + Y(c - c') \in \text{int } \mathbf{K}^*$. Since $\bar{y} \in \mathbf{K}^*$, we conclude that $y^+ \in \text{int } \mathbf{K}^*$. At the same time

$$\begin{aligned} A^*y^+ + R^*z^+ &= [A^*\bar{y} + R^*\bar{z}] + A\Delta y + [A^*Y(c - c') + R^*Z(c - c')] \\ &= c' + (c - c') + A\Delta y = c' + [c - c'] + A^*\Delta y = c + A^*\Delta y = \bar{c}. \end{aligned}$$

We see that (y^+, z^+) is a strictly feasible solution to $(\mathcal{D}[\bar{b}, \bar{c}])$. Since by construction $(\mathcal{P}[\bar{b}, \bar{c}])$ also is strictly feasible, $(\mathcal{P}[\bar{b}, \bar{c}])$ is strictly primal-dual feasible. \square

7.1.5 Sensitivity Analysis

The results we are about to present resemble those of Sensitivity Analysis for LO. Consider a primal-dual pair of cone program in the single-cone form:

$$\min_x \{c^T x : Ax - b \in \mathbf{K}, Rx = r\} \quad (\mathcal{P})$$

along with its dual problem

$$\max_{y,z} \{\langle b, y \rangle + \langle r, z \rangle : y \in \mathbf{K}^*, A^*y + R^*z = c\} \quad (\mathcal{D})$$

In what follows, we treat the part of the data A, b, \mathbf{K}, R as fixed, and b, r, c – as varying, so that it makes sense to refer to (\mathcal{P}) as $(\mathcal{P}[b, r; c])$, and to its dual (\mathcal{D}) as to $(\mathcal{D}[b, r; c])$, and to denote the optimal value of $(\mathcal{P}[b, r; c])$ as $\text{Opt}(b, r; c)$. Our goal is to explore the structure of the *cost function* $\text{Opt}(b, r; c)$ as a function of (b, r) , c being fixed, and of c, b, r being fixed.

The cost function as a function of c

Let $[b; r]$ be fixed at certain value (\bar{b}, \bar{r}) such that $(\mathcal{P}[\bar{b}, \bar{r}; c])$ is feasible (this fact is independent of the value of c). An immediate observation is that in this case, the function $\text{Opt}_{b,r}(c) = \text{Opt}(b, r; c)$ is a concave function of c . Indeed, this is the infimum of the nonempty family $\{f_x(c) = c^T x : Ax - b \in \mathbf{K}, Rx = r\}$ of linear (and thus concave) functions of c . A less trivial observation is as follows:

Proposition 7.1.3 *Let \bar{c} be such that $(\mathcal{P}[\bar{b}, \bar{r}; \bar{c}])$ is solvable, and \bar{x} be the corresponding optimal solution. Then \bar{x} is a supergradient of $\text{Opt}_{\bar{b}, \bar{r}}(\cdot)$ at \bar{c} , meaning that*

$$\forall c : \text{Opt}_{\bar{b}, \bar{r}}(c) \leq \text{Opt}_{\bar{b}, \bar{r}}(\bar{c}) + \bar{x}^T(c - \bar{c}).$$

Geometrically: the graph of $\text{Opt}_{\bar{b}, \bar{r}}(c)$ never goes above the graph of the affine function $\ell(c) = \text{Opt}_{\bar{b}, \bar{r}}(\bar{c}) + \bar{x}^T(c - \bar{c})$ and touches this graph at the point $[\bar{c}; \text{Opt}_{\bar{b}, \bar{r}}(\bar{c})]$ (and perhaps at other points as well).

Proof is immediate: since \bar{x} is a feasible solution of $(\mathcal{P}[\bar{b}, \bar{r}; c])$ for every c , we have

$$\text{Opt}_{\bar{b}, \bar{r}}(c) \leq c^T \bar{x} = (c - \bar{c})^T \bar{x} + \bar{c}^T \bar{x} = \text{Opt}_{\bar{b}, \bar{r}}(\bar{c}) + \bar{x}^T(c - \bar{c}). \quad \square$$

Remark: The fact that a function is convex (or concave) implies, in particular, that the function possesses certain “regularity.” e.g., the following is true:

Let f be a convex (or concave) function and X be a closed and bounded set belonging to the relative interior of function’s domain. Then f is Lipschitz continuous on X : there exists $L < \infty$ such that

$$\forall (x, y \in X) : |f(x) - f(y)| \leq L\|x - y\|.$$

The cost function as a function of (b, r)

Let now c be fixed at certain value \bar{c} , and assume that there exists $[b'; r']$ such that the problem $(\mathcal{P}[b', r'; \bar{c}])$ is strictly feasible and bounded. Then the dual problem $(\mathcal{D}[b', r'; \bar{c}])$ is feasible (and even solvable) by Conic Duality Theorem, meaning that the duals to *all* problems $(\mathcal{D}[b, r; \bar{c}])$ are feasible (since the feasible set of the dual is independent of b, r). By Weak duality, it follows that problems $(\mathcal{P}[b, r; \bar{c}])$ are bounded, and thus the cost function $\text{Opt}_{\bar{c}}(b, r) = \text{Opt}(b, r; \bar{c})$ takes only real values and the value $+\infty$. It is easily seen that this function is convex.

Indeed, denoting for short $q = (b, r)$ and suppressing temporarily the subscript \bar{c} , we should prove that $\text{Opt}((1 - \lambda)q + \lambda q') \leq (1 - \lambda)\text{Opt}(q) + \lambda\text{Opt}(q')$ for all q, q' and all $\lambda \in [0, 1]$. There is nothing to prove when $\lambda = 0$ or $\lambda = 1$; when $0 < \lambda < 1$, there is nothing to prove when $\text{Opt}(q)$ or $\text{Opt}(q')$ are infinite. Thus, we can restrict ourselves with the case $q = (b, r) \in \text{domOpt}$, $q' = (b', r') \in \text{domOpt}$ and $0 < \lambda < 1$. Given $\epsilon > 0$, we can find x and x' such that

$$\begin{aligned} Ax - b &\in \mathbf{K}, Rx = r, \bar{c}^T x \leq \text{Opt}(q) + \epsilon, \\ Ax' - b' &\in \mathbf{K}, Rx' = r, \bar{c}^T x' \leq \text{Opt}(q') + \epsilon. \end{aligned}$$

Setting $\tilde{x} = (1 - \lambda)x + \lambda x'$, $\tilde{q} = (1 - \lambda)q + \lambda q'$, we have $A\tilde{x} - \tilde{q} = (1 - \lambda)[Ax - b] + \lambda[Ax' - b'] \in \mathbf{K}$, where the inclusion follows from the fact that \mathbf{K} is a cone; this, \tilde{q} is a feasible solution for $(\mathcal{P}[\tilde{q}, \bar{c}])$. We also have

$$\begin{aligned} \bar{c}^T \tilde{q} &= (1 - \lambda)\bar{c}^T x + \lambda\bar{c}^T x' \leq (1 - \lambda)[\text{Opt}(q) + \epsilon] + \lambda[\text{Opt}(q') + \epsilon] \\ &= (1 - \lambda)\text{Opt}(q) + \lambda\text{Opt}(q') + \epsilon. \end{aligned}$$

Since \tilde{q} is feasible for $(\mathcal{P}[\tilde{q}, \bar{c}])$, we have

$$\text{Opt}(\tilde{q}) \leq \bar{c}^T \tilde{q} \leq (1 - \lambda)\text{Opt}(q) + \lambda\text{Opt}(q') + \epsilon$$

The resulting inequality holds true for every $\epsilon > 0$, whence

$$\text{Opt}(\tilde{q}) \leq (1 - \lambda)\text{Opt}(q) + \lambda\text{Opt}(q'),$$

which completes the proof of convexity of $\text{Opt}(\cdot)$.

We have the following analogy of Proposition 7.1.3:

Proposition 7.1.4 *Let \bar{b}, \bar{r} be such that $(\mathcal{P}[\bar{b}, \bar{r}, \bar{c}])$ is strictly feasible. Then the dual problem $(\mathcal{D}[\bar{b}, \bar{r}; \bar{c}])$ is solvable, and every optimal solution (\bar{y}, \bar{r}) to the latter program is a subgradient of the convex function $\text{Opt}_{\bar{c}}(\cdot)$ at the point (\bar{b}, \bar{r}) , meaning that*

$$\forall (b, r) : \text{Opt}_{\bar{c}}(b, r) \geq \text{Opt}_{\bar{c}}(\bar{b}, \bar{r}) + \langle \bar{y}, b - \bar{b} \rangle + \langle \bar{z}, r - \bar{r} \rangle.$$

Geometrically: the graph of $\text{Opt}_{\bar{c}}(b, r)$ never goes below the graph of the affine function $\ell(b, r) = \text{Opt}_{\bar{c}}(\bar{b}, \bar{r}) + \langle \bar{y}, b - \bar{b} \rangle + \langle \bar{z}, r - \bar{r} \rangle$ and touches this graph at the point $(\bar{b}, \bar{r}; \text{Opt}_{\bar{c}}(\bar{b}, \bar{r}))$ (and perhaps at other points as well).

Proof is immediate. As we have already mentioned, our choice of \bar{c} ensures that $(\mathcal{D}[\bar{b}, \bar{r}; \bar{c}])$ is feasible, and thus the program $(\mathcal{P}[\bar{b}, \bar{r}, \bar{c}])$ is bounded; since by assumption the latter program is strictly feasible, the Conic Duality Theorem says that $(\mathcal{D}[\bar{b}, \bar{r}; \bar{c}])$ is solvable, which is the first claim in the Proposition. Now let (\bar{y}, \bar{r}) be an optimal solution to $(\mathcal{D}[\bar{b}, \bar{r}; \bar{c}])$. Then for every feasible solution x to $(\mathcal{P}[b, r; \bar{c}])$ we have

$$\begin{aligned} \bar{c}^T x &= [A^* \bar{y} + R^* \bar{z}]^T x = \langle \bar{y}, Ax - b \rangle + \langle \bar{z}, Rx \rangle + \langle \bar{y}, b \rangle \geq \langle \bar{y}, b \rangle + \langle \bar{z}, r \rangle \\ &= \langle \bar{y}, b - \bar{b} \rangle + \langle \bar{z}, r - \bar{r} \rangle + \underbrace{\langle \bar{y}, \bar{b} \rangle + \langle \bar{z}, \bar{r} \rangle}_{=\text{Opt}_{\bar{c}}(\bar{b}, \bar{r})} \end{aligned}$$

Since the resulting inequality is valid for all feasible solutions x to $(\mathcal{P}[b, r; \bar{c}])$, we conclude that

$$\text{Opt}_{\bar{c}}(b, r) \geq \text{Opt}_{\bar{c}}(\bar{b}, \bar{r}) + \langle \bar{y}, b - \bar{b} \rangle + \langle \bar{z}, r - \bar{r} \rangle. \quad \square$$

7.1.6 Geometry of Primal-Dual Pair of Conic Problems

We are about to derive geometric interpretation of a primal-dual pair (P) , (D) of conic programs completely similar to the interpretation of a primal-dual pair of LO programs (section 3.3.2). As was explained in the beginning of section 7.1.2, we lose nothing when assuming that the primal program is a single-cone one and that the space E of the primal decision vectors is \mathbf{R}^n , so that the primal program reads:

$$\text{Opt}(P) = \min_x \{c^T x : Ax - b \in \mathbf{K}, Rx = r\} \quad (P)$$

where $x \mapsto Rx$ is a linear mapping from \mathbf{R}^n to Euclidean space F , and \mathbf{K} is a regular cone in a Euclidean space F_1 which, for aesthetical reasons (we do not need index anymore!), we now denote H . The dual program now reads

$$\text{Opt}(D) = \max_{z,y} \{\langle r, z \rangle + \langle b, y \rangle : y \in \mathbf{K}^*, A^*y + R^*z = c\} \quad (D)$$

(to save notation, we skip the indices in $\langle \cdot, \cdot \rangle$). Assume that the systems of linear equality constraints in (P) and in (D) are solvable, and let \bar{x} and $[\bar{y}; \bar{z}]$ be solutions to these systems:

$$\begin{aligned} (a) \quad & R\bar{x} = r \\ (b) \quad & A^*\bar{y} + R^*\bar{z} = c. \end{aligned} \quad (7.1.10)$$

Let us express (P) in terms of the primal slack $\xi = Ax - b \in H$. The constraints of (P) say that this vector should belong to the intersection of \mathbf{K} and the *primal feasible plane* \mathcal{M}_P which is the image of the affine plane $\{x : Rx = r\}$ in the x -space under the affine mapping $x \mapsto Ax - b$. The linear subspace \mathcal{L}_P in E which is parallel to \mathcal{M}_P is $\mathcal{L}_P = \{\xi = Ax : Rx = 0\}$, and we can take the point $A\bar{x} - b := -\bar{\xi}$ as the shift vector for \mathcal{M}_P . Thus,

$$\mathcal{M}_P = \mathcal{L}_P - \bar{\xi}, \quad \bar{\xi} = b - A\bar{x}, \quad \mathcal{L}_P = \{\xi = Ax : Rx = 0\}. \quad (7.1.11)$$

Now let us express the primal objective in terms of the primal slack. Given x satisfying the equality constraints in (P) , we have (F is the destination space of the mapping $x \mapsto Rx$):

$$\begin{aligned} c^T x &= [A^*\bar{y} + R^*\bar{z}]^T x = [A^*\bar{y}]^T x + [R^*\bar{z}]^T x = \langle \bar{y}, Ax \rangle + \langle Rx, \bar{z} \rangle \\ &= \langle \bar{y}, \underbrace{Ax - b}_{\xi} \rangle + \text{const}_P, \quad \text{const}_P = \langle \bar{y}, b \rangle + \langle r, \bar{z} \rangle. \end{aligned}$$

We have arrived at the following intermediate conclusion:

Program (P) can be reduced to the program

$$\begin{aligned} \text{Opt}(P) &= \min_{\xi \in H} \{\langle \bar{y}, \xi \rangle : \xi \in \mathbf{K} \cap \mathcal{M}_P\} \\ \left[\begin{array}{ll} \mathcal{M}_P &= \mathcal{L}_P - \bar{\xi} := b - A\bar{x} \\ \mathcal{L}_P &= \{\xi = Ax : Rx = 0\} \\ \text{Opt}(P) &= \text{Opt}(P) + \langle \bar{y}, b \rangle + \langle r, \bar{z} \rangle. \end{array} \right] \quad (P) \end{aligned}$$

Now let us process in a similar fashion the dual program (D) , specifically, express it in terms of the vector y . The constraints of (D) say that this vector should belong to the intersection of \mathbf{K}^* and the *dual feasible plane* $\mathcal{M}_D = \{y : \exists z : A^*y + R^*z = c\}$. This plane is parallel to the linear subspace $\mathcal{L}_D = \{y : \exists z : A^*y + R^*z = 0\}$, and as a shift vector for \mathcal{M}_D we can take

$\bar{y} \in \mathcal{M}_D$. It remains to express the dual objective in terms of y . To this end note that if $[y; z]$ satisfies the linear equality constraints of (D), then

$$\begin{aligned} \langle r, z \rangle + \langle b, y \rangle &= \langle R\bar{x}, z \rangle + \langle b, y \rangle = \bar{x}^T [R^*z] + \langle b, y \rangle \\ &= \bar{x}^T [c - A^*y] + \langle b, y \rangle = \bar{x}^T c + \langle b - A\bar{x}, y \rangle = \langle \bar{\xi}, y \rangle + \text{const}_D, \quad \text{const}_D = c^T \bar{x}. \end{aligned}$$

We have arrived at the following conclusion:

Program (D) can be reduced to the program

$$\begin{aligned} \text{Opt}(D) &= \max_{y \in H} \{ \langle \bar{\xi}, y \rangle : y \in \mathbf{K}_* \cap \mathcal{M}_D \} \\ \left[\begin{array}{ll} \mathcal{M}_D &= \mathcal{L}_D + \bar{y} := b - A\bar{x} \\ \mathcal{L}_D &= \{ y : \exists z : A^*y + R^*z = 0 \} \\ \text{Opt}(D) &= \text{Opt}(D) + c^T \bar{x}. \end{array} \right] \quad (D) \end{aligned}$$

Now, same as in the LO case, \mathcal{L}_D is just the orthogonal complement of \mathcal{L}_P . Indeed, $h \in (\mathcal{L}_P)^\perp$ iff $\langle h, Ax \rangle = 0$ whenever $Rx = 0$, that is, iff the linear equation $x^T [A^*h] = 0$ in variables x is a consequence of the linear system $Rx = 0$, which is the case iff $A^*h = R^*w$ for some w , which, after substitution $w = -z$, is nothing but the characterization of \mathcal{L}_D .

Finally, let us compute the duality gap at a pair $(x, [y, z])$ of candidate solutions satisfying the equality constraints in (P) and (D):

$$\begin{aligned} c^T x - \langle b, y \rangle - \langle r, z \rangle &= [A^*y + R^*z]^T x - \langle b, y \rangle - \langle r, z \rangle \\ &= \langle Ax - b, y \rangle + \langle Rx - r, z \rangle = \langle Ax - b, y \rangle. \end{aligned}$$

Putting things together, we arrive at a perfectly symmetric purely geometric description of (P), (D):

Assume that the systems of linear constraints in (P) and (D) are solvable. Then the primal-dual pair (P), (D) of conic problems reduces to the following geometric problem. We are given

- two dual to each other cones \mathbf{K}, \mathbf{K}_* in a Euclidean space H ,
- a pair of linear subspaces $\mathcal{L}_P, \mathcal{L}_D$ in H which are orthogonal complements to each other, and
- a pair of shift vectors $\bar{\xi}, \bar{y}$ in H .

These geometric data define affine subspaces $\mathcal{M}_P = \mathcal{L}_P - \bar{\xi}$, $\mathcal{M}_D = \mathcal{L}_D + \bar{y}$.

The primal problem (P) reduces to minimizing the linear form $\langle \bar{y}, \cdot \rangle$ over the intersection of the primal feasible plane \mathcal{M}_P and the cone \mathbf{K} , which is the primal feasible set; the dual problem (D) reduces to maximizing the linear form $\langle \bar{\xi}, \cdot \rangle$ over the intersection of the dual feasible plane \mathcal{M}_D and the cone \mathbf{K}_ , which is the dual feasible set. Given feasible solutions ξ, y to these geometric problems, the corresponding duality gap is the inner product of the solutions.*

Strict feasibility of a problem from our primal-dual pair means that the corresponding feasible plane intersects the interior of the corresponding cone. Whenever both problems are strictly feasible, the minimal value of the duality gap is zero, and the duality gap, as evaluated at a pair of primal and dual feasible solutions, is the sum of their non-optimality, in terms of the objectives of the respective problems. Under the same assumption of primal-dual strict feasibility, pairs of optimal solutions to the respective problems are exactly the pairs of orthogonal to each other primal and dual feasible solutions, and these pairs do exist.

We see that geometrically, a primal-dual pair of conic problems looks completely similar to a pair of primal-dual LO programs: in both situations (in the second — under additional assumption that both problems are strictly feasible) we are looking for pairs of orthogonal to each other vectors with one member of the pair belonging to the intersection of “primal” affine plane and “primal” cone, and the other member belonging to the intersection of the “dual” affine plane and the “dual” cone.

The pair of primal and dual affine planes cannot be arbitrary: they should be shifts of linear subspaces which are orthogonal complements to each other. Similarly, the pair of cones in question are “rigidly connected” to each other — they are duals of each other. In LO, the underlying cone is the nonnegative orthant and thus is *self-dual*, this is why in our LO investigations (section 3.3.2) we did not see *two* cones, just one of them.

We complete this section by mentioning that, same as in the LO case, the choice of the shift vectors for \mathcal{M}_P , \mathcal{M}_D (or, which is the same, the objectives in (P) and (D)) is immaterial: when replacing the above $\bar{\xi}$ with any other vector from the minus primal feasible plane $[-\mathcal{M}_P]$, the primal problem (P) clearly remains intact, and the dual objective $\langle \bar{\xi}^T, \cdot \rangle$, *restricted on the dual feasible plane*, changes by an additive constant, which affects nothing but the optimal value $\text{Opt}(D)$. By similar reasons, replacing \bar{y} with any other vector from \mathcal{M}_D keeps (D) intact and changes by additive constant the restriction of the primal objective $\langle \bar{y}, \cdot \rangle$ on the primal feasible plane.

7.1.7 Conic Representations of Sets and Functions

It is easily seen that every convex program $\min_{x \in X} f(x)$ ($f : \mathbf{R}^n \rightarrow \mathbf{R}$ is convex, $X \subset \mathbf{R}^n$ is convex and closed) can be equivalently reformulated as a conic program. This fact is of no actual use, since a general-type cone is not simpler than a general-type closed convex set. What indeed is important, is to recognize when a given convex program can be posed as a conic program *from a given family*, primarily — when it can be posed as an LO/CQO/SDO program. To this end we can develop an approach completely similar to the one we used in section 1.2.2. Specifically, assume we are given a family \mathcal{K} of regular cones, every one of them “living” in its own Euclidean space. It makes sense to assume also that the family contains the nonnegative ray and is closed w.r.t. taking finite direct products and to passing from a cone to its dual cone. The most important for us examples are:

- the family \mathcal{LO} of nonnegative orthants; this family underlies LO.
- the family \mathcal{CQO} of finite direct products of Lorentz cones; this family underlies CQO (Conic Quadratic Optimization).
Note that \mathcal{CQO} contains $\mathbf{R}_+ = \mathbf{L}^1$; the fact that all other requirements are satisfied is evident (recall that the Lorentz cones are self-dual).
- the family \mathcal{SDO} of finite direct products of semidefinite cones; this family underlies SDO (Semidefinite Optimization).
Note that \mathcal{SDO} contains $\mathbf{R}_+ = \mathbf{S}_+^1$, and satisfies all other requirements by exactly the same reasons as \mathcal{CQO} .

Now, given a family \mathcal{K} , we call a set $X \subset \mathbf{R}^n$ *\mathcal{K} -representable*, if it can be represented in the form

$$X = \{x \in \mathbf{R}^n : \exists w : Px + Qw + r \in \mathbf{K}\} \quad (!)$$

where \mathbf{K} is a cone from \mathcal{K} ; corresponding data (P, Q, r, \mathbf{K}) , same as the representation itself, are called \mathcal{K} -representation of X (\mathcal{K} -r. of X for short). note that this definition mirrors the definition of a polyhedral representation of a set (which in our now language becomes \mathcal{LO} -representation). Completely similar to the polyhedral case, given a \mathcal{K} -representation (!) of X , we can immediately rewrite the problem of minimizing a linear objective $c^T x$ over X as a conic program on the cone from the family \mathcal{K} , specifically, the program

$$\min_{x,w} \{c^T x : Px + Qw + r \in \mathbf{K}\}.$$

Bearing in mind this observation, we understand why it is important to build a calculus of \mathcal{K} -representable sets and functions. A \mathcal{K} -r. of a function f is, by definition, the same as \mathcal{K} -r. of its epigraph, and a function is called \mathcal{K} -representable, if it admits a \mathcal{K} -r. Same as in the polyhedral case, a \mathcal{K} -r.

$$\{[x; \tau] : \tau \geq f(x)\} = \{[x; \tau] : \exists w : Px + \tau p + Qw + r \in \mathbf{K}\}$$

of a function f implies \mathcal{K} -r.'s of the level sets of the function:

$$\{x : a \geq f(x)\} = \{x : \exists w : Px + ap + Qw + r \in \mathbf{K}\}.$$

The basic calculus rules from section 1.2.3 extend word by word from the polyhedral representability to \mathcal{K} -representability; there are just two facts which, on a close inspection, are responsible for the validity of the calculus rules:

- the fact that, given two systems of linear inequalities (that is, two component-wise vector inequalities $Ax \leq b$ and $Cx \leq d$), we can put them together, thus getting a single vector inequality $[A; B]x \leq [c; d]$. What underlies this fact, is the closedness of the associated family of cones (in the case of polyhedral representability, the family of nonnegative orthants) w.r.t. taking direct products. Since we have required from \mathcal{K} to possess the latter property, putting together two conic inequalities $Ax - b \in \mathbf{K}$ and $A'x - b' \in \mathbf{K}'$ with $\mathbf{K}, \mathbf{K}' \in \mathcal{K}$ results in a single conic inequality $[Ax; A'x] - [b; b'] \in \mathbf{K} \times \mathbf{K}'$ involving a cone from \mathcal{K} .
- the fact that the feasible sets of finite systems of linear inequalities/equations are polyhedrally representable. Since we require from \mathcal{K} to contain rays and to be closed w.r.t. taking direct products, these sets and \mathcal{K} -representable as well.

Extending more advanced rules of calculus of polyhedral representability to the case of \mathcal{K} -representability requires certain care. For example,

1. Assume that an LO program $\min_x \{c^T x : Ax \geq b, Rx = r\}$ is feasible and bounded for some value of $[b; r]$; as we remember from section 3.3.3⁹, under this assumption the function $\text{Opt}([b; r]) = \min_x \{c^T x : Ax \geq b, Rx = r\}$ is convex and polyhedrally representable:

$$\{[b; r; \tau] : \tau \geq \text{Opt}([b; r])\} = \{[b; r; \tau] : \exists x : Ax - b \geq 0, Bx = r, c^T x \leq \tau\}. \quad (!)$$

Now let us pass from the optimal value in a LO program to the one in a conic program: Passing to the optimal value of a \mathcal{K} -conic problem

$$\text{Opt}([b; r]) = \inf \{c^T x : Ax - b \in \mathbf{K}, Bx = r\}. \quad (7.1.12)$$

⁹take into account that in section 3.3.3 we were speaking about the optimal value of a *maximization* problem, while now we are speaking about optimal value of a minimization one; as a result, what used to be concave, now becomes convex.

Assume that the program is strictly feasible and bounded for some value of $[b; r]$. Then the dual program is feasible, and since the latter fact is independent of $[b; r]$, we conclude from Weak duality that (7.1.12) is bounded for all values of $[b; r]$, so that the cost function $\text{Opt}([b; r])$ takes only real values and perhaps the value $+\infty$. You can easily verify that the cost function is convex. Now, the “literal analogy” of (!) would be

$$\{[b; r; \tau] : \tau \geq \text{Opt}([b; r])\} = \{[b; r; \tau] : \exists x : Ax - b \in \mathbf{K}, Bx = r, c^T x \leq \tau\},$$

but this relation is not necessarily true: $\text{Opt}([b; r])$ can be finite and non-achievable, meaning that the fact that the point $[b; r; \tau]$ with $\tau = \text{Opt}([b; r])$ is in the epigraph of Opt cannot be “certified” by any x .

The correct version of (!) is as follows:

Let (7.1.12) be bounded and strictly feasible for some value of $[b; r]$. Then the cost function $\text{Opt}([b; r])$ is a convex function, and the \mathcal{K} -r. set

$$\mathcal{G} = \{[b; r; \tau] : \exists x : Ax - b \in \mathbf{K}, Rx = r, c^T x \leq \tau\}.$$

is in-between the epigraph

$$\text{Epi}(\text{Opt}(\cdot)) = \{[b; r; \tau] : \tau \geq \text{Opt}([b; r])\}$$

of the cost function and the “strictly upper part”

$$\text{Epi}^+(\text{Opt}(\cdot)) = \{[b; r; \tau] : \tau > \text{Opt}([b; r])\}$$

of this epigraph:

$$\text{Epi}^+(\text{Opt}(\cdot)) \subset \mathcal{G} \subset \text{Epi}(\text{Opt}(\cdot)).$$

2. The support function of a nonempty polyhedral set is polyhedrally representable, with a p.r. readily given by a p.r. of the set (section 3.3.3). To get similar result in the general conic case, we need strict feasibility of the representation of the set. The precise statement reads:

Let X be a nonempty \mathcal{K} -representable set given by a \mathcal{K} -representation

$$X = \{x : \exists w : Px + Qw - b \in \mathbf{K}, Rx + Sw = r\} \quad [\mathbf{K} \in \mathcal{K}]$$

which is strictly feasible, meaning that there exists \bar{x}, \bar{w} such that

$$P\bar{x} + Q\bar{w} - b \in \text{int } \mathbf{K}, R\bar{x} + S\bar{w} = r.$$

Then the support function

$$\text{Supp}(\xi) = \sup_{x \in X} \xi^T x$$

of the set X admits the explicit \mathcal{K} -representation

$$\begin{aligned} & \{[\xi; \tau] : \tau \geq \text{Supp}(\xi)\} \\ &= \left\{ [\xi; \tau] : \exists \lambda, \mu : \begin{array}{l} \lambda \in \mathbf{K}^*, P^* \lambda + R^* \mu + \xi = 0, Q^* \lambda + S^* \mu = 0, \\ \langle b, \lambda \rangle + \langle r, \mu \rangle + \tau \geq 0 \end{array} \right\}. \end{aligned} \quad (7.1.13)$$

Note that (7.1.13) indeed is a \mathcal{K} -representation of the support function, since \mathcal{K} is closed w.r.t. passing from a cone to its dual.

Indeed, $-\text{Supp}(\xi)$ is the optimal value in the \mathcal{K} -conic program

$$\min_{x,w} \{-\xi^T x : Px + Qw - b \in \mathbf{K}, Rx + Sw = r\}. \quad (*)$$

The latter problem is strictly feasible; thus, for a real τ , we have $\tau \geq \text{Supp}(\xi)$ iff the latter problem is bounded with the optimal value $\geq -\tau$, which, by Conic Duality Theorem, is the case iff the conic dual of $(*)$ admits a feasible solution with the optimal value $\geq -\tau$, that is, iff

$$\exists \lambda, \mu : \lambda \in \mathbf{K}^*, P^* \lambda + R^* \mu = -\xi, Q^* \lambda + S^* \mu = 0, \langle b, \lambda \rangle + \langle r, \mu \rangle \geq -\tau,$$

and (7.1.13) follows.

Remark: Similar to what was done in section 3.3.3, the possibility to point out a \mathcal{K} -representation of the support function of a (nonempty) \mathcal{K} -r. set implies, along with other consequences, the following result:

Let the (nonempty) uncertainty set of an uncertain LO problem be given by a strictly feasible \mathcal{K} -representation. Then the Robust Counterpart of the problem can be straightforwardly converted into an explicit \mathcal{K} -conic program.

Expressive abilities of \mathcal{CQO} and \mathcal{SDO}

We have seen that the “rule” part of the calculus of \mathcal{K} -representable sets and functions remains intact (and in its “advanced” parts is even slightly weaker) than the calculus of polyhedral representability. What extends *dramatically* when passing from LO to \mathcal{CQO} and especially \mathcal{SDO} , is the spectrum of “raw materials” of the calculus, that is, “elementary” \mathcal{CQO} - and \mathcal{SDO} -representable functions and sets. With slight exaggeration, one can say that “for all practical purposes,” *all* computationally tractable convex sets and functions arising in applications are \mathcal{SDO} -representable, so that all “real life” convex problems are within the grasp of \mathcal{SDO} ¹⁰ In our LO-oriented course, we omit the list of “raw materials” for the calculus of \mathcal{CQO} - and \mathcal{SDO} -representable functions/sets; such a list can be found in [1]. Here we restrict ourselves with a

¹⁰Of course, whatever be a family \mathcal{K} of cones, the \mathcal{K} -representable sets and functions are convex (why?), so that Conic Programming stays within the boundaries of Convex Optimization.

single “advertising example:” the messy and highly nonlinear optimization program

minimize $\sum_{\ell=1}^n x_\ell^2$	
(a)	$x \geq 0;$
(b)	$a_\ell^T x \leq b_\ell, \ell = 1, \dots, n;$
(c)	$\ Px - p\ _2 \leq c^T x + d;$
(d)	$x_\ell^{\frac{\ell+1}{\ell}} \leq e_\ell^T x + f_\ell, \ell = 1, \dots, n;$
(e)	$x_\ell^{\frac{\ell}{\ell+3}} x_{\ell+1}^{\frac{1}{\ell+3}} \geq g_\ell^T x + h_\ell, \ell = 1, \dots, n-1;$
(f)	$\text{Det} \begin{bmatrix} x_1 & x_2 & x_3 & \cdots & x_n \\ x_2 & x_1 & x_2 & \cdots & x_{n-1} \\ x_3 & x_2 & x_1 & \cdots & x_{n-2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ x_n & x_{n-1} & x_{n-2} & \cdots & x_1 \end{bmatrix} \geq 1;$
(g)	$1 \leq \sum_{\ell=1}^n x_\ell \cos(\ell\omega) \leq 1 + \sin^2(5\omega) \forall \omega \in [-\frac{\pi}{7}, 1.3]$

can be converted *in a systematic way* into a semidefinite program; omitting the constraints (f) and (g), the problem can be systematically converted into a \mathcal{CQO} -program (and thus solving it within accuracy ϵ can be reduced in polynomial time to a similar problem for an LO program, see section 1.3.

Remark: In the case of polyhedral representability, ignoring the “compactness” of a representation, we always can avoid slack variables: if a set in \mathbf{R}^n admits a polyhedral representation, it always is polyhedral, i.e., can be represented as the solution set of a system of linear inequalities in the “original” variables – the coordinates of a vector sunning through \mathbf{R}^n . In the non-polyhedral case, using slack variables in representations of sets and functions is a must. For example, take the epigraph of the univariate function x^4 ; this set is conic quadratic representable:

$$G := \{[x, \tau] \in \mathbf{R}^2 : \tau \geq x^4\} = \{[x; \tau] : \exists w \in \mathbf{R} : \underbrace{\|[2x; w-1]\|_2 \leq w+1}_{(a)}, \underbrace{\|[2w; \tau-1]\|_2 \leq \tau+1}_{(b)}\}.$$

Indeed, (a) says that $w \geq x^2$, and (b) says that $\tau \geq w^2$; what these inequalities say about τ, x is exactly $\tau \geq x^4$. On the other hand, assume that we managed to find a conic quadratic representation of the same set without slack variables:

$$G = \{[x; \tau] : \|xa_i + \tau b_i + c_i\|_2 \leq \alpha_i x + \beta_i \tau + \gamma_i, 1 \leq i \leq m, xp + \tau q = r\}. \quad (!)$$

Observe, first, that the system of linear equations should be trivial: $p = q = r = 0$. Indeed, otherwise these equations would cut off the 2D plane of x and τ a line or a point containing G , which clearly is impossible. Now, the sets of the form $\{[x; \tau] : \|xa_i + \tau b_i + c_i\|_2 \leq \alpha_i x + \beta_i \tau + \gamma_i\}$ are convex sets representable as intersections of solutions sets of quadratic inequalities

$$\|xa_i + \tau b_i + c_i\|_2^2 \leq [\alpha_i x + \beta_i \tau + \gamma_i]^2$$

with half-planes (or the entire 2D planes) $\{[x; \tau] : \alpha_i x + \beta_i \tau + \gamma_i \geq 0\}$. A set of this type is bounded by finitely many “arcs,” every one of them being either a line segment (including rays

and entire lines), or parts of ellipses/parabolas/hyperbolas, and thus the right hand side set in (!) is bounded by finitely many arcs of the same type. But such an arc, as it is easily seen, can intersect the true boundary of G – the curve given by $t = x^4$ – only in finitely many points, so that a finite number of the arcs cannot cover the curve. The conclusion is that G cannot represent by conic quadratic inequalities in variables x, τ only.

Relations between LO, CQO and SDO. Clearly, polyhedral representations of sets and functions are their \mathcal{CQO} -m and \mathcal{SDO} -representations as well — recall that the nonnegative ray is the same as the one-dimensional Lorentz and one-dimensional semidefinite cones, so that non-negative orthants “sit” in \mathcal{CQO} and \mathcal{SDO} , as a result, an LO program can be straightforwardly converted into a conic quadratic and into a semidefinite program. For example, the “single-cone” semidefinite reformulation of LO program

$$\min_x \{c^T x : Ax \geq b, Rx = r\} \quad (*)$$

is as follows: keep the objective and the linear equality constraints as they are, and put the entries of the m -dimensional vector $Ax - b$ on the diagonal of a diagonal $m \times m$ matrix $\mathcal{A}(x)$ which, of course, will depend affinely on x . Since a diagonal matrix is symmetric and is positive semidefinite iff its diagonal entries are nonnegative, $(*)$ is equivalent to the SDO program

$$\min_x \{c^T x : \mathcal{A}(x) \succeq 0, Rx = r\}.$$

A less trivial, but still simple, observation is that *conic quadratic representable sets/functions are semidefinite representable as well, with semidefinite representations readily given by conic quadratic ones*. The reason is that a Lorentz cone \mathcal{L}^n is \mathcal{SDO} -representable – it is just the intersection of the semidefinite cone \mathbf{S}_+^n and an appropriate linear subspace of \mathbf{S}^n (this is completely similar to the fact that the nonnegative orthant \mathbf{R}_+^n is the intersection of \mathbf{S}_+^n and the subspace of $n \times n$ diagonal matrices). Specifically, given a vector $x \in \mathbf{R}^n$, let us build the $n \times n$ symmetric matrix

$$\text{Arrow}(x) = \left[\begin{array}{c|cccc} x_n & x_1 & x_2 & \dots & x_n \\ \hline x_2 & x_1 & & & \\ x_3 & & x_1 & & \\ \vdots & & & \ddots & \\ x_n & & & & x_1 \end{array} \right]$$

(blanks are filled with zeros).

Lemma 7.1.2 *Let $x \in \mathbf{R}^n$. The matrix $\text{Arrow}(x)$ is positive semidefinite iff $x \in \mathbf{L}^n$. As a result, a conic quadratic representation of a set*

$$X = \{x : \exists w : A_i x + B_i w + b_i \in \mathcal{L}^{n_i}, 1 \leq i \leq m\}$$

can be converted into a semidefinite representation of the same set, specifically, the representation

$$X = \{x : \exists w : \text{Arrow}(A_i x + B_i w + b_i) \succeq 0, 1 \leq i \leq m\}.$$

Proof. All we need is to prove the equivalence $x \in \mathbf{L}^n \Leftrightarrow \text{Arrow}(x) \succeq 0$. In one direction: assume that $x \in \mathbf{L}^n$, and let us prove that $\text{Arrow}(x) \succeq 0$. The symmetry of $\text{Arrow}(x)$ is evident. To verify positive semidefiniteness, we should prove that $h^T \text{Arrow}(x) h \geq 0$ for all $h \in \mathbf{R}^n$.

Partitioning $h = [g; t]$ with scalar t , and denoting $y = [x_1; \dots; x_{n-1}]$, we have $x_n \geq \|y\|_2$ due to $x \in \mathbf{L}^n$, whence

$$\begin{aligned} h^T \text{Arrow}(x) h &= x_n(t^2 + g^T g) + 2ty^T g \geq x_n(t^2 + g^T g) - 2|t|\|y\|_2\|g\|_2 \geq x_n[t^2 + g^T g - 2|t|\|g\|_2] \\ &= x_n(|t| - \|g\|_2)^2 \geq 0. \end{aligned}$$

In the opposite direction: let $x \in \mathbf{R}^n$ and $\text{Arrow}(x) \succeq 0$, and let us prove that $x \in \mathbf{L}^n$. The statement is evident when $n = 1$, so let $n > 1$. Setting $x = [y; x_n]$, let $h = [g; 1]$, where g is the unit vector such that $g^T y = -\|y\|_2$. Then

$$0 \leq h^T \text{Arrow}(x) h = x_n \|h\|_2^2 + 2 \cdot 1 \cdot g^T y = 2x_n - 2\|y\|_2 = 2[x_n - \|y\|_2].$$

We see that $x_n \geq \|y\|_2$, meaning that $x \in \mathbf{L}^n$. □

Remark. The possibility to convert straightforwardly LO and CQO to Semidefinite Optimization does not mean that this is the best way to solve LOs and CQO's in actual computations. Two former problems are somehow simpler than the latter one, and dedicated LO and CQO solvers available today in commercial packages can solve linear and conic quadratic programs much faster, and in a much wider range of sizes, than “universal” SDO solvers. This being said, when solving “moderate size” LOs and CQOs (what is “moderate,” it depends on “fine structure” of a program being solved and may vary from few hundreds to few thousands of variables), it is very attractive to reduce everything to SDO and thus to use a single solver. This idea is implemented in the `cvx` package¹¹ which uses the calculus of the semidefinite representable sets and functions to convert the input “high level” description of a problem into its “inner” SDO-reformulation which then is forwarded to an SDO solver. The input description of a problem utilizes full capabilities of MATLAB and thus is incredibly transparent and easy to use, making `cvx` an ideal tool for a classroom (and not only for it).

7.2 Interior Point Methods for LO and SDO

In this section we present basic theory of IPM's for LO and SDO. In this presentation, same as everywhere else in this course, we intend to stick to the “grand scheme of things,” without going into algorithmic and implementation details. This allows for unified treatment of IPM's for LO and SDO.

7.2.1 SDO Program and its Dual

In what follows, the problem to be solved is a semidefinite program

$$\min_{x \in \mathbf{R}^n} \left\{ c^T x : \sum_{j=1}^n x_j A_i^j - B_i \succeq 0, i = 1, \dots, m \right\}, \quad (*)$$

where B_i and A_i^j are symmetric $\nu_i \times \nu_i$ matrices.

Note that for notational convenience, we have omitted linear equality constraints which used to be a component of the standard form of a conic program. This can be done without loss of generality. Indeed, we can use the linear equality constraints, if any, to express part of the decision variables as affine functions of the remaining “independent” variables. Substituting these representations in the conic constraints and discarding the linear equality constraints, we end up with an equivalent “equalities-free” reformulation of the original problem.

It is convenient to think about the data matrices B_i , $1 \leq i \leq m$, as about diagonal blocks in a block-diagonal matrix B , and about matrices A_i^j , $1 \leq i \leq m$, as about diagonal blocks in block-diagonal matrices A^j . Since a block-diagonal symmetric matrix is positive semidefinite iff its diagonal blocks are symmetric and positive semidefinite, we can rewrite (*) equivalently as

$$\text{Opt}(P) = \min_x \{ c^T x : \mathcal{A}x - B \in \mathbf{S}_+^\nu \} \quad (P)$$

where

- \mathcal{A} denotes the linear mapping

$$x \mapsto \mathcal{A}x = \sum_{j=1}^N x_j A^j \quad (\mathcal{A})$$

from the space \mathbf{R}^N of the design variables x to the space \mathbf{S}^ν of block-diagonal symmetric matrices of the block-diagonal structure $\nu = [\nu_1; \dots; \nu_m]$, that is, symmetric block-diagonal matrices with m diagonal blocks of sizes ν_1, \dots, ν_m .

- \mathbf{S}_+^ν is the cone of positive semidefinite matrices from \mathbf{S}^ν .

Note that \mathbf{S}^ν clearly is a linear subspace in the space \mathbf{S}^n of $n \times n$ symmetric matrices, where

$$n = |\nu| := \sum_{i=1}^m \nu_i. \quad (7.2.1)$$

\mathbf{S}^ν is equipped with the Frobenius inner product

$$\langle X, S \rangle = \text{Tr}(XS) = \sum_{i,j=1}^n X_{ij} S_{ij} \quad [X, S \in \mathbf{S}^\nu]$$

inherited from \mathbf{S}^n . Note that the cone \mathbf{S}_+^ν is regular and self-dual (why?).

Notational conventions. **I.** We are in the situation when the cone associated with the conic problem we want to solve “lives” in the space \mathbf{S}^ν of matrices. As a result, we need a special notation for linear mappings with \mathbf{S}^ν as the argument or the image space, to distinguish these mappings from matrices “living” in \mathbf{S}^ν . To this end we will use script letters $\mathcal{A}, \mathcal{B}, \dots$ as in (\mathcal{A}) ; matrices from \mathbf{S}^ν , as usual will be denoted by capital Roman letters.

II. As always, we write $A \succeq B$ ($\Leftrightarrow B \preceq A$) to express that A, B are symmetric matrices of the same size such that $A - B$ is positive semidefinite; in particular, $A \succeq 0$ means that A is symmetric positive semidefinite. We write $A \succ B$ ($\Leftrightarrow B \prec A$) to express that A, B are symmetric matrices of the same size such that $A - B$ is positive definite; in particular, $A \succ 0$ means that A is symmetric positive definite. The set of all positive definite matrices from \mathbf{S}^ν is exactly the interior $\text{int } \mathbf{S}_+^\nu$ of the cone \mathbf{S}_+^ν .

III. We shall denote the Euclidean norm associated with the Frobenius inner product by $\|\cdot\|_{\text{Fr}}$:

$$\|A\|_{\text{Fr}} = \sqrt{\langle A, A \rangle} = \sqrt{\text{Tr}(A^2)} = \sqrt{\sum_{i,j} A_{ij}^2} \quad [A \in \mathbf{S}^\nu]$$

Assumption A. From now on we assume that

A. *The linear mapping \mathcal{A} has the trivial kernel, or, which is the same, the matrices A^1, \dots, A^N are linearly independent.*

To justify this assumption, note that when \mathcal{A} has a nontrivial kernel and c is not orthogonal to this kernel, problem (P) definitely is bad — either infeasible, or unbounded. And if c is orthogonal to $\text{Ker } \mathcal{A}$, we lose nothing by restricting x to reside in the orthogonal complement L to $\text{Ker } \mathcal{A}$, which amounts to passing from (P) to an equivalent program of the same structure and with linear mapping possessing trivial kernel.

The problem dual to (P)

The problem dual to the conic problem (P) , according to our general theory, is

$$\text{Opt}(D) = \max_{S \in \mathbf{S}^\nu} \{ \langle B, S \rangle : \mathcal{A}^* S = c, S \in (\mathbf{S}_+^\nu)^* = \mathbf{S}_+^\nu \} \quad (D)$$

where $\mathcal{A}^* : \mathbf{S}^\nu \rightarrow \mathbf{R}^N$ is the linear mapping conjugate to the mapping $\mathcal{A} : \mathbf{R}^N \rightarrow \mathbf{S}^\nu$. Let us compute \mathcal{A}^* . By definition, $\mathcal{A}^* S$ is characterized by the identity

$$\forall x \in \mathbf{R}^N : \langle S, \mathcal{A}x \rangle = x^T [\mathcal{A}^* S].$$

Invoking (\mathcal{A}) , this reads

$$\forall x = [x_1; \dots; x_N] : \sum_{j=1}^N x_j \langle S, A^j \rangle = \sum_{j=1}^N x_j [\mathcal{A}^* S]_j,$$

whence, recalling what $\langle \cdot, \cdot \rangle$ is,

$$\mathcal{A}^* S = [\text{Tr}(A^1 S); \dots; \text{Tr}(A^N S)] \quad (\mathcal{A}^*)$$

In other words, the equality constraints in (D) read $\text{Tr}(A^j S) = c_j$, $1 \leq j \leq N$.

Assumption B. In what follows we, in addition to **A**, make the following crucial assumption:

B. *The primal-dual pair (P) , (D) is primal-dual strictly feasible: there exist \bar{x} and \bar{S} such that*

$$\begin{aligned} \mathcal{A}\bar{x} &\succ 0 \\ \bar{S} &\succ 0 \text{ \& } \mathcal{A}^*\bar{S} = c. \end{aligned} \tag{7.2.2}$$

By Conic Duality Theorem, **B** implies that both (P) and (D) are solvable with equal optimal values.

Geometric form of the primal-dual pair (P) , (D)

By elementary Linear Algebra, assumption **A** ensures solvability of the system of linear constraints in (D) . Denoting by $C \in \mathbf{S}^\nu$ a solution to this system and recalling the construction from section 7.1.6, we can pass from (P) , (D) to geometric reformulations these problems, specifically, to the pair

$$\begin{aligned} \min_X \{ \langle C, X \rangle : X \mathcal{M}_P \cap \in \mathbf{S}_+^\nu \} \\ [C : \mathcal{A}^*C = c, \mathcal{M}_P = \mathcal{L}_P - B, \mathcal{L}_P = \Im \mathcal{A} := \{ \mathcal{A}x : x \in \mathbf{R}^N \}] \end{aligned} \tag{P}$$

$$\begin{aligned} \max_S \{ \langle B, S \rangle : S \mathcal{M}_D \cap \in \mathbf{S}_+^\nu \} \\ [\mathcal{M}_D = \mathcal{L}_D + C, \mathcal{L}_D = \text{Ker } \mathcal{A}^* := \{ S \in \mathbf{S}^\nu : \mathcal{A}^*S = 0 \} = \mathcal{L}_P^\perp] \end{aligned} \tag{D}$$

Recall that

- x is feasible for (P) iff the corresponding primal slack $X(x) = \mathcal{A}x - B$ is feasible for (P) , and $c^T x = \langle C, X(x) \rangle + \langle C, B \rangle$;
- (\mathcal{D}) is nothing but (D) written in the geometric form;
- When x is feasible for (P) and S is feasible for (D) , the corresponding duality gap satisfies

$$\text{DualityGap}(x, S) := c^T x - \langle B, S \rangle = \langle X(x), S \rangle; \tag{7.2.3}$$

- A pair of optimal solutions to (\mathcal{P}) , (\mathcal{D}) is exactly a pair of orthogonal to each other feasible solutions to the respective problems. A pair x, S of optimal solutions to (P) , (D) is exactly a pair of feasible solutions to the respective problems such that $X(x)$ is orthogonal to S .

7.2.2 Path-Following Interior Point methods for (P) , (D) : preliminaries

Log-Det Barrier

In what follows, the central role is played by the *log-det barrier* for the cone \mathbf{S}_+^ν — the function

$$\Phi(X) = -\ln \text{Det } X : \text{int } \mathbf{S}_+^\nu \rightarrow \mathbf{R}. \tag{7.2.4}$$

This function is clearly well defined and smooth (has derivatives of all orders) on the interior $\text{int } \mathbf{S}_+^\nu$ of the positive semidefinite cone; we extend Φ from this interior to the entire \mathbf{S}^ν by setting $\Phi(X) = +\infty$ when $X \notin \text{Dom } \Phi := \text{int } \mathbf{S}_+^\nu$, obtaining, on the closest inspection, a convex function (it was shown in section 3.3.4, see p. 139). We are about to list the most important in our context properties of this barrier. It will be very instructive for a reader to “translate” these properties to the case of LO, which is nothing but the case of simple block-diagonal structure

$\nu = [1; \dots; 1]$, where \mathbf{S}^ν is just the space of $n \times n$ diagonal matrices, or, identifying such a matrix with the vector of its diagonal entries, just \mathbf{R}^n . With this identification, \mathbf{S}_+^ν is nothing but the nonnegative orthant \mathbf{R}_+^n , and the log-det barrier becomes the log-barrier

$$F(x) = - \sum_{i=1}^n \ln(x_i) : \text{int } \mathbf{R}_+^n \rightarrow \mathbf{R}.$$

I. Barrier property: *Whenever $\{X_i\}$ is a sequence of points from $\text{Dom } \Phi = \text{int } \mathbf{S}_+^n$ (i.e., a sequence of positive definite matrices) converging to a matrix $X \in \partial \text{Dom } \Phi$ (i.e., converging to a positive semidefinite and singular matrix), we have $\Phi(X_i) \rightarrow +\infty$ as $i \rightarrow \infty$.*

This property is evident: the vector of eigenvalues $\lambda(X)$ of X (see p. 139) is the limit of the vectors $\lambda(X_i)$, and since X is positive semidefinite, but not positive definite matrix, some of $\lambda_j(X)$ are zeros. Thus, some of the n sequences $\{\lambda_j(X_i)\}_{i=1}^\infty$, $1 \leq j \leq n$, have zero limits, while the remaining have positive limits, whence

$$\Phi(X_i) = -\log \text{Det}(X_i) = - \sum_{j=1}^n \ln(\lambda_j(X_i)) \rightarrow +\infty, i \rightarrow \infty. \quad \square$$

II. Derivatives of Φ : *Let $X \succ 0$. Then the gradient $\nabla \Phi(X)$ of Φ at X is*

$$\nabla \Phi(X) = -X^{-1} \quad (7.2.5)$$

and the Hessian $\mathcal{H}(X) = \nabla \Phi'(X)$ (which is a self-conjugate linear mapping acting from \mathbf{S}^ν to \mathbf{S}^ν , see p. 326 in Appendix) is given by

$$\mathcal{H}(X)H = X^{-1}HX, H \in \mathbf{S}^\nu. \quad (7.2.6)$$

For derivation of these formulas, see Appendix, p. 322 and p. 327.

III. Strong convexity of Φ on its domain: *For every $X \in \text{Dom } \Phi$, we have*

$$\forall H \in \mathbf{S}^\nu : \langle H, \mathcal{H}(X)H \rangle = \|X^{-1/2}HX^{-1/2}\|_{\text{Fr}}^2 \geq 0, \quad (7.2.7)$$

with the concluding inequality being strict unless $H = 0$.

Indeed, we have

$$\begin{aligned} \langle H, \mathcal{H}(X)H \rangle &= \text{Tr}(HX^{-1}HX^{-1}) \underbrace{=}_{(a)} \text{Tr}([HX^{-1}HX^{-1/2}]X^{-1/2}) \\ &= \text{Tr}(X^{-1/2}[HX^{-1}HX^{-1/2}]) = \text{Tr}([X^{-1/2}HX^{-1/2}]^2), \end{aligned}$$

where (a) is given by the simple and important fact we have already mentioned: *whenever A and B are such that AB is well defined and is square, we have $\text{Tr}(AB) = \text{Tr}(BA)$.*

IV. “Self-Duality” of Φ and basic identities: We have

- [“Self-duality”] The mapping $X \mapsto -\nabla \Phi(X) = X^{-1}$ is a one-to-one mapping of $\text{int } \mathbf{S}_+^\nu$ onto itself which is self-inverse: $-\nabla \Phi(-\nabla \Phi(X)) = (X^{-1})^{-1} = X$ for all $X \succ 0$.

- [“Basic identities”] For $X \in \text{Dom } \Phi$ we have

$$\begin{aligned} (a) \quad & \langle X, \nabla \Phi(X) \rangle = -n := \sum_{i=1}^m \nu_i; \\ (b) \quad & \nabla \Phi(X) = -\mathcal{H}(X)X; \\ (c) \quad & \nabla \Phi(tX) = t^{-1} \nabla \Phi(X). \end{aligned} \tag{7.2.8}$$

Indeed, by (7.2.5) $\langle X, \nabla \Phi(X) \rangle = \text{Tr}(X[-X^{-1}]) = \text{Tr}(-I_n) = -n$, while by (7.2.6) and (7.2.5) $\nabla \Phi(X) = -X^{-1} = -X^{-1}XX^{-1} = -\mathcal{H}(X)X$. We have proved (a) and (b); (c) is evident due to $\nabla \Phi(X) = -X^{-1}$.

Path-Following Scheme: the Idea

The idea underlying the IPMs we are about to consider is as follows. Let $\mu > 0$. Consider the *penalized primal objective*, the *penalty parameter* being μ — the function

$$P_\mu(X) := \langle C, X \rangle + \mu \Phi(X) : \mathcal{M}_P^+ := \mathcal{M}_P \cap \text{int } \mathbf{S}_+^\nu \rightarrow \mathbf{R}.$$

Thus is a smooth convex function on the strictly feasible part \mathcal{M}^+ of the feasible set of (\mathcal{P}) which has the *barrier property* — it blows up to $+\infty$ along every sequence of strictly feasible solutions to (\mathcal{P}) converging to a boundary point of \mathcal{M}_P^+ (i.e., to a feasible solution which is a degenerate matrix; in the LO case, this is a feasible solution with not all the coordinates strictly positive). Assume that this function attains its minimum over \mathcal{M}_P^+ at a unique point $X = X_*(\mu)$ (as we shall see in a while, this indeed is the case). We arrive at a curve $X_*(\mu)$, $\mu > 0$, in the space of strictly feasible solutions to (\mathcal{P}) . called the *primal central path*. Now, what happens when $\mu \rightarrow +0$? When μ is small, the function $P_\mu(X)$ is close to the primal objective $\langle C, X \rangle$ in “almost entire” set \mathcal{M}_P^+ of strictly feasible solutions to (\mathcal{P}) , that is, everywhere in the set \mathcal{M}_P^+ except for a narrow “strip” along the relative boundary $\partial \mathcal{M}_P^+ = \{X \in \mathcal{M}_P \cap \mathbf{S}_+^\nu : \text{Det}(X) = 0\}$ of the set where $\Phi(X)$ is so large that the penalty term $\mu \Phi(X)$ is “non-negligible.” As $\mu \rightarrow +0$, this stripe becomes more and more thin, so that ‘ $P_\mu(X)$ becomes more and more close to the primal objective in a larger and larger part of the set \mathcal{M}_P^+ of strictly feasible primal solutions. As a result, it is natural to expect (and indeed is true) that *the primal central path approaches the primal optimal set as $\mu \rightarrow 0$* — it is a kind of Ariadne’s thread leading to the primal optimal set, see figure 7.1. In the path-following IPM, we *move along this path, staying “close” to it* — exactly as Theseus used Ariadne’s thread — *and thus approach the optimal set*. How we “move along the path staying close to it,” this will be explained later. What is worthy of noting tight now, is that the dual problem (\mathcal{D}) , which is in no sense inferior to (\mathcal{P}) , also defines a path, called the *dual central path*, which leads to the dual optimal set. It turns out that it makes full sense to follow both the paths *simultaneously* (these two processes “help each other”), thus approaching both primal and dual optimal solutions.

7.2.3 Central Path: Existence and Characterization

Proposition 7.2.1 *Under Assumption B of strict primal-dual feasibility, for every $\mu > 0$ the functions*

$$\begin{aligned} P_\mu(X) &= \langle C, X \rangle + \mu \Phi(X) : \mathcal{M}_P^+ := \mathcal{M}_P \cap \text{int } \mathbf{S}_+^\nu \rightarrow \mathbf{R} \\ D_\mu(S) &= -\langle B, S \rangle + \mu \Phi(S) : \mathcal{M}_D^+ := \mathcal{M}_D \cap \text{int } \mathbf{S}_+^\nu \rightarrow \mathbf{R} \end{aligned}$$

the respective minimizers $X_(\mu)$ and $S_*(\mu)$ being unique. These minimizers $X_* = X_*(\mu)$ and $S_* = S_*(\mu)$ are fully characterized by the following property: X_* is a strictly feasible solution*

Figure 7.1: 2D primal feasible set $\mathcal{M}_P \cap \mathbf{S}_+^4$ and the primal central path

to (\mathcal{P}) , S_* as a strictly feasible solution to (\mathcal{D}) , and the following four equivalent to each other relations take place:

$$\begin{aligned}
& S_* = \mu X_*^{-1} \quad [\Leftrightarrow S_* = -\mu \nabla \Phi(X_*)] \quad (a) \\
\Leftrightarrow & X_* = \mu S_*^{-1} \quad [\Leftrightarrow X_* = -\mu \nabla \Phi(S_*)] \quad (b) \\
& X_* S_* = \mu I \quad (c) \\
& S_* X_* = \mu I \quad (d) \\
\Leftrightarrow & X_* S_* + S_* X_* = 2\mu I \quad (e)
\end{aligned} \tag{7.2.9}$$

Proof. 1^0 . Let us prove first that $P_\mu(\cdot)$ achieves its minimum at \mathcal{M}_P^+ . Indeed, let X_i be a minimizing sequence for P_μ , that is, $X_i \in \mathcal{M}_P^+$ and

$$P_\mu(X_i) \rightarrow \inf_{X \in \mathcal{M}_P^+} P_\mu(X), \quad i \rightarrow \infty.$$

All we need is to prove that the sequence $\{X_i\}$ is bounded. Indeed, taking this fact for granted, we could extract from the sequence a converging subsequence; w.l.o.g., let it be the sequence itself: $\exists \bar{X} = \lim_{i \rightarrow \infty} X_i$. We claim that $\bar{X} \in \mathcal{M}_P^+$, which would imply that \bar{X} is a desired minimizer of $\Phi_\mu(\cdot)$ on \mathcal{M}_P^+ . Indeed the only alternative to $\bar{X} \in \mathcal{M}_P^+$ is that \bar{X} is a boundary point of \mathcal{S}_+^ν ; but in this case $\Phi(X_i) \rightarrow \infty$ as $i \rightarrow \infty$ due to the barrier property of Φ , while the sequence $\langle B, X_i \rangle$ is bounded since the sequence $\{X_i\}$ is so. It would follow that $P_\mu(X_i) \rightarrow +\infty$ as $i \rightarrow \infty$, which contradicts the origin of the sequence $\{X_i\}$.

It remains to verify our claim that the sequence $\{X_i\}$ is bounded. To this end note that, as we remember from section 7.1.6, when we replace C (which by its origin belongs to the dual feasible plane $\mathcal{M}_D = \{S : \mathcal{A}^* S = c\}$, see (\mathcal{P}) , (\mathcal{D})) with any other point $C' \in \mathcal{M}_D$, the primal objective, restricted to the primal feasible plane \mathcal{M}_P , is shifted by a constant, meaning that $\{X_i\}$ is a minimizing sequence for the function $P'_\mu(X) = \langle C', X \rangle + \mu \Phi(X)$ on \mathcal{M}_P^+ . Since (\mathcal{D}) is strictly feasible, we can choose C' to be $\succ 0$, which, by Lemma 7.1.1 and due to the fact that \mathcal{S}_+^ν is self-dual, implies that $\|X\|_{\text{Fr}} \leq \theta \langle C', X \rangle$ for some θ and all $X \in \mathcal{S}_+^\nu$. Assuming that $\|X_i\|_{\text{Fr}} \rightarrow \infty$ as $i \rightarrow \infty$ and taking into account that $\Phi(X) \geq -\ln(m\|X\|_{\text{Fr}})$ when $\text{int } \mathcal{S}_+^\nu$ (why?), we would conclude that

$$P'_\mu(X_i) = \langle C', X_i \rangle + \mu \Phi(X_i) \geq \theta^{-1} \|X_i\|_{\text{Fr}} - \mu \ln(m\|X_i\|_{\text{Fr}}) \rightarrow \infty, \quad i \rightarrow \infty,$$

which contradicts to the fact that $\{X_i\}$ is a minimizing sequence for $P'_\mu(\cdot)$ on \mathcal{M}_P^+ . This contradiction shows that the sequence $\{X_i\}$ is bounded, as claimed.

2^0 Now let us prove that the minimizer of $P_\mu(\cdot)$ on \mathcal{M}_P^+ is unique. This is immediately given by the fact that \mathcal{M}_P^+ is convex and $P_\mu(\cdot)$ is strongly convex along with Φ .

Since we do not assume previous knowledge of continuous optimization, here is the verification. Assume that X', X'' are two distinct minimizers of $P_\mu(\cdot)$ on \mathcal{M}_P^+ , and let us lead this assumption to a contradiction. To this end let $H = X'' - X'$, $X_t = X' + tH$ and $\phi(t) = P_\mu(X_t)$, $0 \leq t \leq 1$. Computing $\phi''(t)$, we get $\phi''(t) = \langle H, \mathcal{H}(X_t)H \rangle > 0$, see item **III** in section 7.2.2. At the same time, ϕ attains its minimum on $[0, 1]$ at 0 and at 1 due to the origin of X' and X'' . Since $\phi(0) \leq \phi(t)$ for $t \in [0, 1]$, $\phi'(0) \geq 0$, and since $\phi(t) \geq \phi(1)$ for $t \in [0, 1]$, $\phi'(1) \leq 0$. But this is impossible, since $\phi'(1) = \phi'(0) + \int_0^1 \phi''(t) dt > \phi'(0)$.

3^0 We have proved that the minimizer X_* of $P_\mu(\cdot)$ on \mathcal{M}_P^+ exists and is unique. By exactly the same argument but applied to (\mathcal{D}) instead of (\mathcal{P}) , the minimizer $S_* = S_*(\mu)$ of $D_\mu(\cdot)$ on \mathcal{M}_D^+

exists and is unique. Now, for every $H \in \mathcal{L}_P$ a segment $\{X_* + tH, -\delta \leq t \leq \Delta\}$ is contained in \mathcal{M}_P^+ provided $\delta > 0$ is small enough; indeed, this segment clearly is contained in \mathcal{M}_P for all δ and is comprised of positive definite matrices for small enough $\delta > 0$ due to $X_* \succ 0$. Applying the Fermat rule, we see that the directional derivative $DP_\mu(X_*)[H] = \frac{d}{dt}\big|_{t=0} P_\mu(X_* + tH) = \langle C - \mu \nabla \Phi(X_*), H \rangle$ of $P_\mu(X_*)$ taken at X_* along the direction H should be 0, and this should be so for every $H \in \mathcal{L}_P$, meaning that the gradient $\nabla P_\mu(X_*)$ should be orthogonal to \mathcal{L}_P and thus should belong to $\mathcal{L}_D = \mathcal{L}_P^\perp$. Vice versa, if $\bar{X} \in \mathcal{M}_P^+$ is such that $\nabla P_\mu(\bar{X}) \in \mathcal{L}_P^\perp$, then, taking into account that $P_\mu(\cdot)$ is convex on \mathcal{M}_P^+ along with $\Phi(\cdot)$ (see the beginning of section 7.2.2) and applying Gradient inequality, we conclude that \bar{X} is a minimizer of $P_\mu(\cdot)$ over \mathcal{M}_P^+ . The bottom line is as follows: X_* is fully characterized by the fact that it is a strictly feasible solution to (\mathcal{P}) such that $C + \mu \nabla \Phi(X_*) = C - \mu X_*^{-1} \in \mathcal{L}_P^\perp = \mathcal{L}_D$. Since $X_*^{-1} \succ 0$ due to $X_* \succ 0$, recalling the definition of the dual feasible plane, this conclusion can be reformulated as follows:

(!) $X_* = X_*(\mu)$ is fully characterized by the fact that it is a strictly feasible solution to (\mathcal{P}) such that $\mu X_*^{-1} \equiv -\mu \nabla \Phi(X_*)$ is a strictly feasible solution to (\mathcal{D}) .

By similar argument,

(!!) $S_* = S_*(\mu)$ is fully characterized by the fact that it is a strictly feasible solution to (\mathcal{P}) such that $\mu S_*^{-1} \equiv -\mu \nabla \Phi(S_*)$ is a strictly feasible solution to (\mathcal{P}) .

Now note that the “strictly feasible solution to (\mathcal{D}) ” mentioned in (!) is nothing but S_* . Indeed, setting temporary $\hat{S} = \mu X_*^{-1}$, we get a strictly feasible solution to (\mathcal{D}) such that $\mu \hat{S}^{-1} = X_*$ is a strictly feasible solution to (\mathcal{P}) ; but by (!!), these two facts fully characterize S_* , and we conclude that $S_* = \mu X_*^{-1}$.

⁴⁰ We have proved that $X_* = X_*(\mu)$, $S_* = S_*(\mu)$ are fully characterized by the facts that they are strictly feasible solutions to the respective problems (\mathcal{P}) , (\mathcal{D}) and are linked to each other by any one of the first four (clearly equivalent to each other) relations in (7.2.9). It remains to verify that these four relations, taken along with the fact that X_* and S_* are positive definite, are equivalent to the fifth relation in (7.2.9). To this end it clearly suffices to verify that if X, S are positive semidefinite symmetric matrices such that $SX + XS = 2tI$ with certain real t , then the matrices commute: $SX = XS$, so that $SX = XS = tI$. Indeed, from $SX + XS = 2tI$ it follows that $X^2S = 2tX - XSX$ is a symmetric matrix, that is, $X^2S = (X^2S)^T = SX^2$, i.e., the symmetric matrices X^2 and S commute. By Theorem on simultaneous diagonalization of commuting symmetric matrices (Appendix, p. 331), there exist orthogonal matrix U such that both the matrices $USU^T = P$ and $UX^2U^T = Q$ are diagonal (and positive semidefinite along with S, X). Setting $R = Q^{1/2}$, consider the matrices $S = U^T P U$ and $\bar{X} = U^T R U$. These matrices clearly commute, so that all which we need to prove is that in fact $\bar{X} = X$. But this is evident: by construction, $\bar{X} \succeq 0$ and $\bar{X}^2 = U^T [Q^{1/2}]^2 U = X^2$, that is, $\bar{X} = (X^2)^{1/2}$; but the latter matrix is nothing but X due to $X \succeq 0$. \square

Primal-dual central path. We have proved that the primal and the dual central paths $X_*(\mu)$, $S_*(\mu)$ are well defined. In the sequel, we refer to $(X_*(\cdot), S_*(\cdot))$ as to *primal-dual central path* of the strictly primal-dual feasible primal-dual pair (\mathcal{P}) , (\mathcal{D}) of semidefinite programs. By the origin of (\mathcal{P}) , $X_*(\mu) = \mathcal{A}x_*(\mu)$ for uniquely defined (by assumption **A**) path $x_*(\mu)$ of feasible solutions to (P) .

Augmented Complementary Slackness. The equivalent to each other relations (7.2.9.c-e) are called *augmented complementary slackness conditions*. The reason is clear: the necessary and sufficient condition for a pair of primal-dual feasible solutions (X, S) to (\mathcal{P}) , (\mathcal{D}) be comprised of optimal solutions is $\text{Tr}(XS) = 0$, or, which is the same for symmetric positive semidefinite matrices, $XS = SX = 0$ ¹². Relations (7.2.9.c-e) replace $XS = 0$ with a close, for small $\mu > 0$, relation $XS = \mu I$, which allow X and S to be positive definite.

7.2.4 Duality Gap along the Primal-Dual Central Path and around it

We start with the following immediate

Observation 7.2.1 *The duality gap along the primal-dual central path is equal to μn , $n = \sum_i \nu_i$:*

$$\forall \mu > 0 : \text{DualityGap}(X_*(\mu), S_*(\mu)) := c^T x_*(\mu) - \langle B, S_*(\mu) \rangle = \langle X_*(\mu), S_*(\mu) \rangle = \mu n. \quad (7.2.10)$$

Indeed, the first equality in (7.2.10) is explained in section 7.1.6, and the second equality is due to the definition of the Frobenius inner product and (7.2.9).

Observation 7.2.1 shows that if we were able to move along the primal-dual central path pushing μ to $+0$, we were approaching primal-dual optimality at the rate depending solely on the rate at which μ approaches 0. Unfortunately, the primal-dual central path is a curve, and there is no possibility to stay at it all the time. What we intend to do, is to trace this path, staying close to it. Immediate related questions are

- A. What kind of closeness is appropriate for us?
- B. How to trace the path staying “appropriately close” to it?

Here we answer question A; question B, which is the essence of the matter, will be answered in the next section.

Proximity measure. A good, by far not evident in advance, is offered by the proximity measure as follows:

Given a target value $\mu > 0$ of the path parameter and a pair $Z = (X, S)$ of strictly feasible solutions to (\mathcal{P}) , (\mathcal{D}) , we quantify the closeness of (X, S) to $Z_(\mu) = (X_*(\mu), S_*(\mu))$ by the quantity*

$$\begin{aligned} \text{dist}(Z, Z_*(\mu)) &= \sqrt{\langle [\mu^{-1}S - X], [\mathcal{H}(X)]^{-1}[\mu^{-1}S - X^{-1}] \rangle} \\ &= \sqrt{\text{Tr}(X[\mu^{-1}S - X^{-1}]X[\mu^{-1}S - X^{-1}])}. \end{aligned} \quad (7.2.11)$$

Observe that this “strange” proximity measure is well defined: $\mathcal{H}(X)$, due to its origin, is a symmetric positive definite mapping of \mathcal{S}^ν onto itself, so that the quantity under the square root always is nonnegative and is 0 iff $S = \mu X^{-1}$ – the equality which, for strongly feasible

¹²The equivalence is shown as follows: Let $X \succeq 0$, $S \succeq 0$; we should prove that $\text{Tr}(XS) = 0$ iff $XS = 0$ and $SX = 0$. In one direction this is evident: if $XS = 0$, then also $SX = (XS)^T = 0$, and vice versa, and of course in this case $\text{Tr}(XS) = 0$. In the opposite direction: assume that $\text{Tr}(XS) = 0$. Then $0 = \text{Tr}(XS) = \text{Tr}(X^{1/2}SX^{1/2}) = \text{Tr}((X^{1/2}S^{1/2})(X^{1/2}S^{1/2})^T) = \|X^{1/2}S^{1/2}\|_{\text{Fr}}^2$, whence $X^{1/2}S^{1/2} = 0$, so that $S^{1/2}X^{1/2} = (X^{1/2}S^{1/2})^T = 0$ as well. We see that the matrices $X^{1/2}$ and $S^{1/2}$ commute and their product is 0, whence also $XS = (X^{1/2})^2(S^{1/2})^2 = X^{1/2}S^{1/2}S^{1/2}X^{1/2} = 0$.

solutions to (\mathcal{P}) , (\mathcal{D}) , characterizes the pair $X_*(\mu)$, $S_*(\mu)$. Note also that the above “distance,” which looks asymmetric w.r.t. X and S , is in fact perfectly symmetric:

$$\begin{aligned} \text{Tr}(X[\mu^{-1}S - X^{-1}]X[\mu^{-1}S - X^{-1}]) &= \text{Tr}([\mu^{-1}XS - I][\mu^{-1}XS - I]) \\ &= \text{Tr}(\mu^{-2}XSXS - 2\mu^{-1}XS + I) = \text{Tr}(\mu^{-2}SXSX - 2\mu^{-1}SX + I) \\ &= \text{Tr}([\mu^{-1}SX - I][\mu^{-1}SX - I]) = \text{Tr}(S[\mu^{-1}X - S^{-1}]S[\mu^{-1}X - S^{-1}]). \end{aligned}$$

Besides recovering the symmetry w.r.t. X, S , this computation shows also that

$$\begin{aligned} \text{dist}^2((X, S), Z_*(\mu)) &= \text{Tr}(\mu^{-2}XSXS - 2\mu^{-1}XS + I) \\ &= \text{Tr}(\mu^{-2}X^{1/2}SX^{1/2}SX^{1/2} - 2\mu X^{1/2}SX^{1/2} + I) \\ &= \text{Tr}([\mu^{-1}X^{1/2}SX^{1/2} - I]^2) = \|\mu^{-1}X^{1/2}SX^{1/2} - I\|_{\text{Fr}}^2; \end{aligned}$$

taking into account the symmetry, we arrive at

$$\text{dist}^2((X, S), Z_*(t)) = \|\mu^{-1}X^{1/2}SX^{1/2} - I\|_{\text{Fr}}^2 = \|\mu^{-1}S^{1/2}XS^{1/2} - I\|_{\text{Fr}}^2. \quad (7.2.12)$$

We extract from these relations an important

Corollary 7.2.1 *Let $Z = (X, S)$ be a pair of strictly feasible solutions to (\mathcal{P}) , (\mathcal{D}) . Then*

$$\text{DualityGap}(X, S) \leq \mu n(1 + \rho/\sqrt{n}), \quad \rho = \text{dist}((X, S), (X_*(\mu), S_*(\mu))). \quad (7.2.13)$$

Indeed, the matrix $R = \mu^{-1}X^{1/2}SX^{1/2} - I$ is symmetric, and $\rho^2 = \sum_{i,j} R_{ij}^2 \geq \sum_i R_{ii}^2$, whence $\sum_i R_{ii} \leq \rho\sqrt{n}$. In other words,

$$\text{DualityGap}(X, S) = \text{Tr}(XS) = \text{Tr}(X^{1/2}SX^{1/2}) = \mu \sum_{i=1}^n (1 + R_{ii}) \leq \mu n + \mu \rho \sqrt{n}. \quad \square$$

In the sequel, we shall say that a pair (X, S) close to $Z_*(\mu) = (X_*(\mu), S_*(\mu))$, if X is strictly feasible solution to \mathcal{P} , S is strictly feasible solution to (\mathcal{D}) , and

$$\text{dist}((X, S), Z_*(\mu)) \leq 0.1.$$

Corollary 7.2.1 says that as far as the duality gap is concerned, a pair of primal-dual strictly feasible solutions (X, S) which is close to $(X_*(\mu), S_*(\mu))$ is essentially as good as the latter pair itself:

$$\text{DualityGap}(X, S) \leq 1.1\mu n.$$

Thus, it is wise to *trace* the path as $\mu \rightarrow +0$ – to build a sequence of triples (X_i, S_i, μ_i) with (X_i, S_i) close to $Z_*(\mu_i)$ and $\mu_i \rightarrow 0$ as $i \rightarrow \infty$. The rate of convergence of such a scheme depends solely on the rate at which we can push μ_i to 0.

Conceptual Path-Following Scheme

Assume we are given a current value $\bar{\mu} > 0$ of the path parameter and a current iterate (\bar{X}, \bar{S}) close to $Z_*(\bar{\mu})$. How could we decrease the value of μ to a smaller value $\mu_+ > 0$ and to update (\bar{X}, \bar{S}) into a new iterate (X_+, S_+) close to $Z_*(\mu_+)$? If we knew an answer to this question, we could iterate the updating $(\bar{X}, \bar{S}, \bar{\mu}) \mapsto (X_+, S_+, \mu_+)$, thus hopefully obtaining a converging algorithm.

Assume that we have somehow chosen $\mu_+ > 0$. Denoting $\Delta\bar{X} = X_+ - \bar{X}$, $\Delta S = S_+ - \bar{S}$, these two matrices should satisfy the following restrictions:

$$\begin{aligned} (a) \quad & \Delta X \in \mathcal{L}_P \\ (a') \quad & \bar{X} + \Delta X \succ 0 \\ (b) \quad & \Delta S \in \mathcal{L}_D = \mathcal{L}_P^\perp \\ (b') \quad & \bar{S} + \Delta S \succ 0 \\ (c) \quad & G_{\mu_+}(\bar{X} + \Delta X, \bar{S} + \Delta S) \approx 0. \end{aligned} \tag{7.2.14}$$

Here (a), (a') ensure that $X_+ = \bar{X} + \Delta X$ is strictly primal feasible, (b), (b') ensure that $S_+ = \bar{S} + \Delta S$ strictly dual feasible, and $G_{\mu_+}(X, S)$ represents equivalently the augmented complementary slackness condition $\mu_+^{-1}S - X^{-1} = 0$, so that (c) is responsible for closeness of (X_+, S_+) to $Z_*(\mu_+)$.

Now, (a) and (b) are just linear equality constraints, and we know from Linear Algebra how to handle them. Since (a') and (b') are *strict* conic inequalities which are satisfied when $\Delta X = 0$, $\Delta S = 0$, they will be automatically satisfied when ΔX and ΔS are small enough, which we can hope to ensure by decreasing μ “not too aggressively” – by choosing $\mu_+ < \bar{\mu}$ close enough to $\bar{\mu}$. What is an actual troublemaker, is (c) — this is a system of *nonlinear* inequalities. Well, in Computational Mathematics there is a standard way to cope with nonlinearity of systems of equations we want to solve — *lumbarization*. Given current iterate, we linearize the equations of the system at this iterate and solve the resulting system of *linear equations*, treating the resulting solution as our new iterate. The rationale behind this approach, called the *Newton method* (it indeed goes back to Newton) is that if we already are close to a solution to the true system, then the linearized system will be “very close” to the true one, so that the new iterate will be “much closer” to the actual solution than the previous one. When replacing (7.2.15) with the lumbarization of the augmented complementary slackness condition taken at “previous iterate” $\Delta X = 0$, $\Delta S = 0$, we end up with the system of linear equations in variables ΔX , ΔS

$$\begin{aligned} (a) \quad & \Delta X \in \mathcal{L}_P \\ (b) \quad & \Delta S \in \mathcal{L}_D = \mathcal{L}_P^\perp \\ (c) \quad & G_{\mu_+}(\bar{X}, \bar{S}) + \frac{\partial G_{\mu_+}(\bar{X}, \bar{S})}{\partial X} \Delta X + \frac{\partial G_{\mu_+}(\bar{X}, \bar{S})}{\partial S} \Delta S = 0. \end{aligned} \tag{7.2.15}$$

augmented by \succ -inequalities

$$\bar{x} + \Delta X \succ 0, \bar{S} + \Delta S \succ 0 \tag{7.2.16}$$

At a step of a “simple” path-following method, given current value $\bar{\mu} > 0$ of the path parameter along with current strictly primal-dual feasible iterate (\bar{X}, \bar{S}) , we

- choose a new value $\mu_+ > 0$ of the path parameter,
- form and solve the system (7.2.15) of linear equations in matrix variables ΔX , ΔS , and
- update the iterate according to $(\bar{X}, \bar{S}) \mapsto (X_+ = \bar{X} + \Delta X, S_+ = \bar{S} + \Delta S)$

and go to the next step (i.e., replace $\bar{X}, \bar{S}, \bar{\mu}$ with X_+, S_+, μ_+ and repeat the above actions. In such a method, the care on \succ -inequalities (7.2.16) comes from the construction of the method – it should be such that these inequalities are automatically satisfied. In more advanced methods, the solution ΔX , ΔS to (7.2.15) plays the role of *search direction* rather than the actual shift in the iterates; the new iterates are given by

$$X_+ = \bar{X} + \alpha \Delta X, \quad S_+ = \bar{S} + \alpha \Delta S, \tag{!}$$

where $\alpha > 0$ is a stepsize chosen according to rules (different in different methods) which include, in particular, the requirement that (!) preserves positive definiteness. With this modification, the restrictions (7.2.16) become redundant and are eliminated.

Primal path-following method

Let us look what happens when we use in (7.2.15) the augmented complementary slackness condition in its initial form

$$G_{\mu_+}(\bar{X} + \Delta X, \bar{S} + \Delta S) := \mu_+^{-1}[\bar{S} + \Delta S] - [\bar{X} + \Delta X]^{-1} = 0. \quad (*)$$

In this case, recalling that $-(\bar{X} + \Delta X)^{-1} = \nabla \Phi(\bar{X} + \Delta X) \approx \nabla \Phi(\bar{X}) + \mathcal{H}(\bar{X})\Delta X$ and taking into account item II in section 7.2.2, relation (7.2.15.c) reads

$$\mu_+^{-1}(\bar{S} + \Delta S) - \bar{X}^{-1} + \bar{X}^{-1}\Delta X\bar{X}^{-1} = 0,$$

so that (7.2.15) becomes the system

$$\begin{aligned} (a) \quad \Delta X &\in \mathcal{L}_P & \Leftrightarrow \quad \Delta X &= \mathcal{A}\delta x \quad [\Delta x \in \mathbf{R}^N] \\ (b) \quad \Delta S &\in \mathcal{L}_D & \Leftrightarrow \quad \mathcal{A}^*\Delta L &= 0 \\ (c) \quad \mu_+^{-1}[\bar{S} + \Delta S] - \bar{X}^{-1} + \bar{X}^{-1}\Delta X\bar{X}^{-1} &= 0 \end{aligned} \quad (\text{Nwt})$$

(we have used the description of \mathcal{L}_P and \mathcal{L}_D as given in (\mathcal{P}) , (\mathcal{D})). To process the system, we act as follows. We set

$$K(x) = \Phi(X(x)) \equiv \Phi(\mathcal{A}x - B),$$

thus getting a barrier for the feasible domain of (P) ; note that for a strictly feasible solution x to (P) we have

$$\nabla K(x) = \mathcal{A}^*\nabla \Phi(X(x)), \nabla^2 K(x)h = \mathcal{A}^*\mathcal{H}(X(x))\mathcal{A}h \quad [X(x) = \mathcal{A}x - B]$$

Let also \bar{x} be the strictly feasible solution to (P) corresponding to the strictly feasible solution \bar{X} to (\mathcal{P}) :

$$\bar{X} = X(\bar{x}) = \mathcal{A}\bar{x} - B.$$

Multiplying both sides in (Nwt.c) by \mathcal{A}^* and taking into account that $\mathcal{A}^*(\bar{S} + \Delta S) = c$ (since \bar{S} is dual feasible and ΔS should satisfy $\mathcal{A}^*\Delta S = 0$), we get the equation

$$\nabla^2 K(\bar{x})\delta x + \nabla K(\bar{x}) + \mu_+^{-1}c = 0 \quad (*)$$

in variable $\Delta x \in \mathbf{R}^n$. It is immediately seen that assumption **A** and strong convexity of Φ (item III in section 7.2.2) ensure that $\nabla^2 K(\bar{x})$ is positive definite and thus nonsingular, and we can solve $(*)$ thus getting

$$\begin{aligned} \delta x &= -[\nabla^2 K(\bar{x})]^{-1}[\nabla K(\bar{x}) + \mu_+^{-1}c] \\ \Rightarrow \quad X_+ &= X(\bar{x} + \Delta x) = \mathcal{A}[\bar{x} + \Delta x] - B \\ S_+ &= S + \Delta S = \mu_+[\bar{X}^{-1} + \mathcal{H}(\bar{X})\mathcal{A}\Delta x]. \end{aligned}$$

We see that this process can be expressed in terms of the original decision variables $x \in \mathbf{R}^N$ and the barrier $K(x)$ for the feasible domain of (P) . Iterating this process, we arrive at the *primal*

path-following method where the iterates x_i in the space of original decision variables and the values μ_i of the path parameter are updated according to

$$\begin{aligned} (a) \quad & \mu_i \mapsto \mu_{i+1} > 0 \\ (b) \quad & x_i \mapsto x_{i+1} = x_i - [\nabla^2 K(x_i)]^{-1} [\nabla K(x_i) + \mu_{i+1}^{-1} c] \end{aligned} \quad (7.2.17)$$

and this process is accompanied by generating primal slacks X_{i+1} and dual solutions S_{i+1} according to

$$\begin{aligned} X_{i+1} &= X(x_{i+1}) = \mathcal{A}x_{i+1} - B \\ S_{i+1} &= \mu_{i+1} [X_i^{-1} + X_i^{-1}[\mathcal{A}[x_{i+1} - x_i]X_i^{-1}]] \end{aligned} \quad (7.2.18)$$

Note that the relation (7.2.17.b) is quite transparent. Indeed, the original design variables $x \in \mathbf{R}^N$ affinely parameterize the primal feasible plane \mathcal{M}_P in (\mathcal{P}) according to $X = X(x) = \mathcal{A}x - B$, and the objective $\langle C, X \rangle$ of (\mathcal{P}) in this parameterization, up to an irrelevant additive constant, is the original objective $c^T x$. With this parameterization, the set \mathcal{M}_P^+ of strictly feasible solutions to (\mathcal{P}) is parameterized by the interior $\text{int } \mathcal{X}$ of the feasible domain $\mathcal{X} = \{X : \mathcal{A}x - B \in \mathcal{M}_P^+\}$ of (P) , and the primal central path $X_*(\mu)$ is parameterized by the primal central path $x_*(\mu) \in \text{int } \mathcal{X}$ in the space of x -variables. Now, $X_*(\mu)$ minimizes $\langle C, X \rangle + \mu\Phi(X)$ over $X \in \mathcal{M}_P^+$, meaning that $x_*(\mu)$ minimizes $c^T x + \mu\Phi(\mathcal{A}x - B) = c^T x + \mu K(x)$ over $x \in \text{int } \mathcal{X}$. In other words, $x_*(\mu)$ is given by the Fermat equation

$$\nabla K(x) + \mu c = 0;$$

Linearizing this equation (where μ is set to μ_{i+1}) at i -th iterate $x_i \in \text{int } \mathcal{X}$, we get the Newton equation for x_{i+1} :

$$\nabla K(x_i) + \nabla^2 K(x_{i+1})(x_{i+1} - x_i) + \mu_{i+1}c = 0.$$

Solving this equation with respect to x_{i+1} , we arrive at the recurrence (7.2.17.b).

Note: With the augmented complementary slackness relation $G_{\mu_+}(X, S) = 0$ rewritten in the form $\mu_+^{-1}X - S^{-1} = 0$, the construction completely similar to one we have just presented leads to the *dual path-following method* which, essentially is the primal path-following algorithms as applied to the “swapped” pair (\mathcal{D}) , (\mathcal{P}) of problems.

The complexity analysis of the primal path-following method can be summarized in the following statement (we omit its proof):

Theorem 7.2.1 *Assume that we are given a starting point (x_0, S_0, μ_0) such that x_0 is a strictly feasible solution to (P) , S_0 is a strictly feasible solution to (\mathcal{D}) , $\mu_0 > 0$ and the pair*

$$(X_0 = \mathcal{A}x_0 - B, S_0)$$

is close to $Z_(\mu_0)$:*

$$\text{dist}((X_0, S_0), Z_*(\mu_0)) \leq 0.1.$$

Starting with (μ_0, x_0, X_0, S_0) , let us iterate process (7.2.17) – (7.2.18) equipped with the updating policy for μ_i given by

$$\mu_{i+1} = \left(1 + \frac{0.1}{\sqrt{n}}\right)^{-1} \mu_i \quad [n = \sum_{i=1}^m \nu_i] \quad (7.2.19)$$

The resulting process is well-defined and generates strictly primal-dual feasible pairs (X_i, S_i) such that (X_i, S_i) stay close to the points $Z_(\mu_i)$ on the primal-dual central path:*

$$\text{dist}((X_i, S_i), Z_*(\mu_i)) \leq 0.1, \quad i = 1, 2, \dots \quad (7.2.20)$$

The theorem says that getting once close to the primal-dual central path, we can trace it by the primal path-following method, keeping the iterates close to the path (see (7.2.20)) and decreasing the penalty parameter by an absolute constant factor every $O(1)\sqrt{n}$ steps. Taking into account Corollary 7.2.1 we conclude that

$$\text{DualityGap}(X_i, S_i) \leq 1.1n\mu_0 \exp\{-O(1)i/\sqrt{n}\}, \quad (7.2.21)$$

that is,

(!) *Every $O(1)\sqrt{n}$ iterations of the method reduce the (upper bound on the) duality gap by an absolute constant factor, say, by factor 10.*

This fact is extremely important theoretically; in particular, it underlies the best known so far RACM-polynomial time complexity bounds for LO, CQO and SDO. As a practical tool, the primal at least in their short-step form presented above, are not that attractive. The computational power of the methods can be improved by passing to appropriate large-step versions of the algorithms, but even these versions are thought of to be inferior as compared to “true” primal-dual path-following methods (those which “indeed work with both (\mathcal{P}) and (\mathcal{D}) ”, see below). There are, however, cases when the primal or the dual path-following scheme seems to be unavoidable; these are, essentially, the situations where the pair $(\mathcal{P}), (\mathcal{D})$ is “highly asymmetric”, e.g., (\mathcal{P}) and (\mathcal{D}) have different by orders of magnitude design dimensions $\dim \mathcal{L}_P$, $\dim \mathcal{L}_D$. Here it becomes too expensive computationally to treat $(\mathcal{P}), (\mathcal{D})$ in a “nearly symmetric way”, and it is better to focus solely on the problem with smaller design dimension.

7.2.5 Primal-Dual Path-Following methods

Zhang’s family of path-following IPMs

The augmented complementary slackness condition can be written in several equivalent forms, e.g., $\mu^{-1}S - X^{-1} = 0$, $\mu^{-1}X - S^{-1} = 0$, or $XS + SX = 2\mu^{-1}I$. What the word “equivalence” means here is that the “positive definite parts” (those where $X \succ 0, S \succ 0$) of the solution sets of the above matrix equations coincide with each other. Note, however, that we are interested in *approximate* solutions to these equations and in *linearizations* of the equations taken at these approximate solutions, and from this viewpoint different “equivalent” forms of the augmented complementary slackness condition are not equivalent at all and lead to different path-following algorithms.

Let us focus on the *Zhang’s family* of representations of the augmented complementary slackness condition. Specifically, given $\mu > 0$ and a positive definite matrix $Q \in \mathbf{S}^\nu$, let us look at the equation

$$QXSQ^{-1} + Q^{-1}SXQ = 2\mu I. \quad (7.2.22)$$

in symmetric matrix variables $X, S \in \mathbf{S}^\nu$. We claim that *positive definite* solutions X, S to this equation are exactly positive definite X, S satisfying the augmented complementary slackness condition $XS = \mu I$.

In one direction our claim is evident: if $X \succ 0, S \succ 0$ satisfy $XS = \mu I$, then, of course, X, S are positive definite solutions to (7.2.22). Vice versa, let X, S be positive definite solutions to (7.2.22), and let us prove that $XS = \mu I$. to this end let $\hat{X} = QXQ$ and $\tilde{S} = Q^{-1}SQ^{-1}$; since Q, S, X are symmetric positive definite, so are \hat{X} and \tilde{S} . We have

$$\hat{X}\tilde{S} + \tilde{S}\hat{X} = [QXQ][Q^{-1}SQ^{-1}] + [Q^{-1}SQ^{-1}][QXQ] = QXSQ^{-1} + Q^{-1}SXQ = 2\mu I,$$

where the last equality is due to (7.2.22). But when proving Proposition 7.2.1, we have seen that if a pair of positive definite symmetric matrices \hat{X} , \tilde{S} satisfies the relation $\hat{X}\tilde{S} + \tilde{S}\hat{X} = 2\mu I$, then $\hat{X}\tilde{S} = \mu I$, that is, $QXSQ^{-1} = \mu I$, which is the same as $XS = \mu I$.

We can use the representation (7.2.22) of the augmented complementary slackness condition in a path-following method, even varying the *scaling matrix* Q from step to step. Analysis of such a method simplifies dramatically when the matrix $Q \succ 0$ we choose at an iteration ensures that the matrices

$$\tilde{S} = Q^{-1}\bar{S}Q^{-1}, \quad \hat{X} = Q\bar{X}Q$$

commute (\bar{X}, \bar{S} are the iterates to be updated); such a policy is called a “commutative scaling.” Popular commutative scalings are:

1. $Q = \bar{S}^{1/2}$ ($\tilde{S} = I, \hat{X} = \bar{S}^{1/2}\bar{X}\bar{S}^{1/2}$) (the “ XS ” method);
2. $Q = \bar{X}^{-1/2}$ ($\tilde{S} = \bar{X}^{1/2}\bar{S}\bar{X}^{1/2}, \hat{X} = I$) (the “ SX ” method);
3. Q is such that $\tilde{S} = \hat{X}$ (the NT (Nesterov-Todd) method, extremely attractive and deep)

If \bar{X} and \bar{S} were just positive reals, the formula for Q would be simple: $Q = \left(\frac{\bar{S}}{\bar{X}}\right)^{1/4}$.

In the matrix case this simple formula becomes a bit more complicated (to make our life easier, below we write X instead of \bar{X} and S instead of \bar{S}):

$$Q = P^{1/2}, \quad P = X^{-1/2}(X^{1/2}SX^{1/2})^{-1/2}X^{1/2}S.$$

We should verify that (a) P is symmetric positive definite, so that Q is well-defined, and that (b) $Q^{-1}SQ^{-1} = QXQ$.

(a): Let us first verify that P is symmetric:

$$\begin{aligned} P & \stackrel{?}{=} P^T \\ & \Updownarrow \\ X^{-1/2}(X^{1/2}SX^{1/2})^{-1/2}X^{1/2}S & \stackrel{?}{=} SX^{1/2}(X^{1/2}SX^{1/2})^{-1/2}X^{-1/2} \\ & \Updownarrow \\ (X^{-1/2}(X^{1/2}SX^{1/2})^{-1/2}X^{1/2}S) & (X^{1/2}(X^{1/2}SX^{1/2})^{1/2}X^{-1/2}S^{-1}) \stackrel{?}{=} I \\ & \Updownarrow \\ X^{-1/2}(X^{1/2}SX^{1/2})^{-1/2}(X^{1/2}SX^{1/2}) & (X^{1/2}SX^{1/2})^{1/2}X^{-1/2}S^{-1} \stackrel{?}{=} I \\ & \Updownarrow \\ X^{-1/2}(X^{1/2}SX^{1/2}) & X^{-1/2}S^{-1} \stackrel{?}{=} I \end{aligned}$$

and the concluding $\stackrel{?}{=} I$ indeed is $=$.

Now let us verify that P is positive definite. It is known from Linear Algebra that the spectrum (the set of distinct eigenvalues) of the product AB of two square matrices remains unchanged when we swap the factors¹³. Therefore, denoting $\sigma(A)$ the spectrum

¹³Here is the verification: If $\lambda = 0$ is an eigenvalue of AB , then the matrix AB is singular, that is, $\text{Det}(AB) = 0$, whence $\text{Det}(BA) = 0$ and thus BA is singular, meaning that $\lambda = 0$ is an eigenvalue of BA as well. Now let $\lambda \neq 0$ be an eigenvalue of AB . Assume that λ is not an eigenvalue of BA , and let us lead this assumption to a contradiction. Setting $R = I + \lambda^{-1}A[I - \lambda^{-1}BA]^{-1}B$, we have $R[I - \lambda^{-1}AB] = [I - \lambda^{-1}AB] + \lambda^{-1}A[I - \lambda^{-1}BA]^{-1}(B[I - \lambda^{-1}AB]) = [I - \lambda^{-1}AB] + \lambda^{-1}A[I - \lambda^{-1}BA]^{-1}[I - \lambda^{-1}BA]B = [I - \lambda^{-1}AB] + \lambda^{-1}AB = I$, that is, $[I - \lambda^{-1}AB]$ is invertible, which is impossible since λ is an eigenvalue of AB .

of A , we have

$$\begin{aligned}
 \sigma(P) &= \sigma \left(X^{-1/2} (X^{1/2} S X^{1/2})^{-1/2} X^{1/2} S \right) \\
 &= \sigma \left((X^{1/2} S X^{1/2})^{-1/2} X^{1/2} S X^{-1/2} \right) \\
 &= \sigma \left((X^{1/2} S X^{1/2})^{-1/2} (X^{1/2} S X^{1/2}) X^{-1} \right) \\
 &= \sigma \left((X^{1/2} S X^{1/2})^{1/2} X^{-1} \right) \\
 &= \sigma \left(X^{-1/2} (X^{1/2} S X^{1/2})^{1/2} X^{-1/2} \right),
 \end{aligned}$$

and the argument of the concluding $\sigma(\cdot)$ clearly is a positive definite symmetric matrix. Thus, the spectrum of *symmetric* matrix P is positive, i.e., P is positive definite.

(b): To verify that $QXQ = Q^{-1}SQ^{-1}$, i.e., that $P^{1/2}XP^{1/2} = P^{-1/2}SP^{-1/2}$, is the same as to verify that $PXP = S$. The latter equality is given by the following computation:

$$\begin{aligned}
 PXP &= (X^{-1/2} (X^{1/2} S X^{1/2})^{-1/2} X^{1/2} S) X (X^{-1/2} (X^{1/2} S X^{1/2})^{-1/2} X^{1/2} S) \\
 &= X^{-1/2} (X^{1/2} S X^{1/2})^{-1/2} (X^{1/2} S X^{1/2}) (X^{1/2} S X^{1/2})^{-1/2} X^{1/2} S \\
 &= X^{-1/2} X^{1/2} S \\
 &= S.
 \end{aligned}$$

You should not think that Nesterov and Todd guessed the formula for this scaling matrix. They did much more: they have developed an extremely deep theory (covering the general LO-CQO-SDO case, not just the SDP one!) which, among other things, guarantees that the desired scaling matrix exists (and even is unique). After the existence is established, it becomes much easier (although still not that easy) to find an explicit formula for Q .

Primal-dual short-step path-following methods based on commutative scalings

Path-following methods we are about to consider trace the primal-dual central path of (\mathcal{P}) , (\mathcal{D}) , staying close to it. The path is traced by iterating the following updating:

(U): Given a current pair of strictly feasible primal and dual solutions (\bar{X}, \bar{S}) such that the triple

$$(\bar{\mu} = n^{-1} \text{Tr}(\bar{X}\bar{S}), \bar{X}, \bar{S}) \quad (7.2.23)$$

satisfies $\text{dist}((\bar{X}, \bar{S}), Z_*(\bar{t})) \leq \kappa \leq 0.1$, or, equivalently, (see (7.2.12))

$$\|\bar{t}\bar{X}^{1/2}\bar{S}\bar{X}^{1/2} - I\|_{\text{Fr}} \leq \kappa, \quad (7.2.24)$$

we

1. Choose the new value μ_+ of the path parameter according to

$$\mu_+ = \left(1 - \frac{\chi}{\sqrt{n}}\right) \bar{t}, \quad n = \sum_{i=1}^m \nu_i; \quad (7.2.25)$$

2. Choose somehow the scaling matrix $Q \succ 0$ such that the matrices $\hat{X} = Q\bar{X}Q$ and $\tilde{S} = Q^{-1}\bar{S}Q^{-1}$ commute with each other;
3. Linearize the equation

$$QXSQ^{-1} + Q^{-1}SXQ = 2\mu_+I$$

at the point (\bar{X}, \bar{S}) , thus coming to the equation

$$Q[\Delta XS + X\Delta S]Q^{-1} + Q^{-1}[\Delta SX + S\Delta X]Q = 2\mu_+I - [Q\bar{X}\bar{S}Q^{-1} + Q^{-1}\bar{S}\bar{X}Q]; \quad (7.2.26)$$

4. Add to (7.2.26) the linear equations

$$\begin{aligned}\Delta X &\in \mathcal{L}_P, \\ \Delta S &\in \mathcal{L}_D = \mathcal{L}_P^\perp;\end{aligned}\tag{7.2.27}$$

5. Solve system (7.2.26), (7.2.27), thus getting “primal-dual search direction” $(\Delta X, \Delta S)$;
 6. Update current primal-dual solutions (\bar{X}, \bar{S}) into a new pair (X_+, S_+) according to

$$X_+ = \bar{X} + \Delta X, \quad S_+ = \bar{S} + \Delta S.$$

We already have explained the ideas underlying (U), up to the fact that in our previous explanations we dealt with three “independent” entities $\bar{\mu}$ (current value of the path parameter), \bar{X} , \bar{S} (current strictly feasible primal and dual solutions), while in (U) $\bar{\mu}$ is a function of \bar{X}, \bar{S} :

$$\bar{\mu} = n^{-1} \text{Tr}(\bar{X}\bar{S}).\tag{7.2.28}$$

The reason for establishing this dependence is very simple: if (μ, X, S) were on the primal-dual central path: $XS = \mu I$, then, taking traces, we indeed would get $\mu = n^{-1} \text{Tr}(XS)$. Thus, (7.2.28) is a reasonable way to reduce the number of “independent entities” we deal with.

Note also that (U) is a “pure Newton scheme” ΔX and ΔS are used as shifts $X_+ - \bar{X}$, $S_+ - \bar{S}$ rather than as search directions.-

The major element of the complexity analysis of path-following polynomial time methods for LO and SDO is as follows:

Theorem 7.2.2 *Let $0 < \chi \leq \kappa \leq 0.1$. Let, further, (\bar{X}, \bar{S}) be a pair of strictly feasible primal and dual solutions to (\mathcal{P}) , (\mathcal{D}) such that the triple (7.2.23) satisfies (7.2.24). Then the updated pair (X_+, S_+) is well-defined (i.e., system (7.2.26), (7.2.27) is solvable with a unique solution), X_+, S_+ are strictly feasible solutions to (\mathcal{P}) , (\mathcal{D}) , respectively,*

$$\mu_+ = n^{-1} \text{Tr}(X_+ S_+)$$

and the triple (μ_+, X_+, S_+) is close to the path:

$$\text{dist}((X_+, S_+), Z_*(\mu_+)) \leq \kappa.$$

Discussion. The theorem says that updating (U) converts a close to the primal-dual central path, in the sense of (7.2.24), strictly primal-dual feasible iterate (\bar{X}, \bar{S}) into a new strictly primal-dual feasible iterate with the same closeness-to-the-path property and smaller, by factor $(1 - \chi n^{-1/2})$, value of the path parameter. Thus, after we once get close to the path, we are able to trace this path, staying close to it and decreasing the path parameter by absolute constant factor in $O(1)\sqrt{n}$ steps. According to Corollary 7.2.1, this means that every $O(1)\sqrt{n}$ steps decrease the (upper bound on the) duality gap by absolute constant factor.

Note that path-following methods implemented in software work *more or less* according to the outlined scheme, up to the fact that they decrease the path parameter more aggressively and move in an essentially larger neighbourhood of the central path than the short-step methods we have described. From the theoretical worst-case-oriented viewpoint, this “aggressive behavior” is dangerous and can result in decreasing the duality gap by an absolute constant factor at the cost of $O(n)$ iterations, rather than of $O(\sqrt{n})$ of them. In actual computations, however, this aggressive policy outperforms significantly the worst-case-oriented “safe short-step policy.”

***Proof of Theorem 7.2.2**

We are about to carry out the complexity analysis of the primal-dual path-following methods based on “commutative” Zhang’s scalings. This analysis, although not that difficult, is more technical than whatever else in our course, and a non-interested reader may skip it without any harm.

Scalings. Let Q be a nonsingular matrix of the same size and block-diagonal structure as those of the matrices from \mathbf{S}^ν . We can associate with Q a one-to-one linear transformation on \mathbf{S}^ν (“scaling by Q ”) given by the formula

$$H \mapsto \mathcal{Q}[H] = QHQ^T. \quad (\text{Scl})$$

It is immediately seen that (Scl) is a symmetry of the semidefinite cone \mathbf{S}_+^ν , meaning that it maps the cone onto itself, same as it maps onto itself the interior of the cone. This family of symmetries is quite rich: for every pair of points A, B from the interior of the semidefinite cone, there exists a scaling which maps A onto B , e.g., the scaling

$$H \mapsto \underbrace{(B^{1/2}A^{-1/2})}_Q H \underbrace{(A^{-1/2}B^{1/2})}_{Q^T}.$$

Essentially, this is exactly the existence of that rich family of symmetries of the underlying cones which makes SDO (same as LO and CQO, where the cones also are “perfectly symmetric”) especially well suited for IP methods.

In what follows we will be interested in scalings associated with *positive definite* scaling matrices from \mathbf{S}^ν . The scaling given by such a matrix Q (X, S, \dots) will be denoted by \mathcal{Q} (resp., $\mathcal{X}, \mathcal{S}, \dots$):

$$\mathcal{Q}[H] = QHQ.$$

Given a problem of interest (P) and a scaling matrix $Q \succ 0$, we can *scale* the problem, i.e., pass from it to the problem

$$\min_x \{c^T x : \mathcal{Q}[Ax - B] \succeq 0\} \quad (\mathcal{Q}(P))$$

which, of course, is equivalent to (P) (since $\mathcal{Q}[H]$ is positive semidefinite iff H is so). In terms of “geometric reformulation” (\mathcal{P}) of (P), this transformation is nothing but the substitution of variables

$$QXQ = Y \Leftrightarrow X = Q^{-1}YQ^{-1};$$

with respect to Y -variables, (\mathcal{P}) is the problem

$$\min_Y \left\{ \text{Tr}(C[Q^{-1}YQ^{-1}]) : Y \in \widehat{\mathcal{M}}_P := \mathcal{Q}[\mathcal{L}_P] - \mathcal{Q}[B], Y \in \mathbf{S}_+^\nu \right\},$$

i.e., the problem

$$\begin{aligned} & \min_Y \left\{ \text{Tr}(\tilde{C}Y) : Y \in \widehat{\mathcal{M}}_P := \widehat{\mathcal{L}}_P - \widehat{B}, Y \in \mathbf{S}^\nu \right\} \\ & \left[\tilde{C} = Q^{-1}CQ^{-1}, \widehat{B} = QBQ, \widehat{\mathcal{L}}_P = \text{Im}(\mathcal{Q} \cdot A) = \mathcal{Q}[\mathcal{L}_P] := \{\mathcal{Q}[H] : H \in \mathcal{L}_P\} \right] \end{aligned} \quad (\widehat{\mathcal{P}})$$

The problem dual to ($\widehat{\mathcal{P}}$) is

$$\max_Z \left\{ \text{Tr}(\widehat{B}Z) : Z \in \widehat{\mathcal{L}}_P^\perp + \widehat{C}, Z \in \mathbf{S}_+^\nu \right\}. \quad (\widetilde{\mathcal{D}})$$

It is immediate to realize what is $\widehat{\mathcal{L}}_P^\perp$:

$$\langle Z, QXQ \rangle = \text{Tr}(ZQXQ) = \text{Tr}(QZQX) = \langle QZQ, X \rangle;$$

thus, Z is orthogonal to every matrix from $\widehat{\mathcal{L}}_P$, i.e., to every matrix of the form QXQ with $X \in \mathcal{L}_P$ iff the matrix QZQ is orthogonal to every matrix from \mathcal{L}_P , i.e., iff $QZQ \in \mathcal{L}_P^\perp$. It follows that

$$\widehat{\mathcal{L}}_P^\perp = \mathcal{Q}^{-1}[\mathcal{L}_P^\perp].$$

Thus, when acting on the primal-dual pair $(\mathcal{P}), (\mathcal{D})$ of SDO programs, a scaling, given by a matrix $Q \succ 0$, converts it into another primal-dual pair of problems, and this new pair is as follows:

- The “primal” geometric data – the subspace \mathcal{L}_P and the primal shift B (which has a part-time job to be the dual objective as well) – are replaced with their images under the mapping \mathcal{Q} ;
- The “dual” geometric data – the subspace $\mathcal{L}_D = \mathcal{L}_P^\perp$ and the dual shift C (it is the primal objective as well) – are replaced with their images under the mapping \mathcal{Q}^{-1} inverse to \mathcal{Q} ; this inverse mapping again is a scaling, the scaling matrix being Q^{-1} .

We see that it makes sense to speak about *primal-dual scaling* which acts on both the primal and the dual variables and maps a primal variable X onto QXQ , and a dual variable S onto $Q^{-1}SQ^{-1}$. Formally speaking, the primal-dual scaling associated with a matrix $Q \succ 0$ is the linear transformation $(X, S) \mapsto (QXQ, Q^{-1}SQ^{-1})$ of the direct product of two copies of \mathbf{S}^n (the “primal” and the “dual” ones). A primal-dual scaling acts naturally on different entities associated with a primal-dual pair $(\mathcal{P}), (\mathcal{D})$, in particular, at:

- the pair $(\mathcal{P}), (\mathcal{D})$ itself – it is converted into another primal-dual pair of problems $(\widehat{\mathcal{P}}), (\widehat{\mathcal{D}})$;
- a primal-dual feasible pair (X, S) of solutions to $(\mathcal{P}), (\mathcal{D})$ – it is converted to the pair $(\widehat{X} = QXQ, \widehat{S} = Q^{-1}SQ^{-1})$, which, as it is immediately seen, is a pair of feasible solutions to $(\widehat{\mathcal{P}}), (\widehat{\mathcal{D}})$. Note that the primal-dual scaling preserves strict feasibility and the duality gap:

$$\text{DualityGap}_{\mathcal{P}, \mathcal{D}}(X, S) = \text{Tr}(XS) = \text{Tr}(QXSQ^{-1}) = \text{Tr}(\widehat{X}\widehat{S}) = \text{DualityGap}_{\widehat{\mathcal{P}}, \widehat{\mathcal{D}}}(\widehat{X}, \widehat{S});$$

- the primal-dual central path $(X_*(\cdot), S_*(\cdot))$ of $(\mathcal{P}), (\mathcal{D})$; it is converted into the curve $(\widehat{X}_*(\mu) = QX_*(\mu)Q, \widehat{S}_*(\mu) = Q^{-1}S_*(\mu)Q^{-1})$, which is nothing but the primal-dual central path $\widehat{Z}(\mu)$ of the primal-dual pair $(\widehat{\mathcal{P}}), (\widehat{\mathcal{D}})$.

The latter fact can be easily derived from the characterization of the primal-dual central path; a more instructive derivation is based on the fact that our “hero” – the barrier $\Phi(\cdot)$ – is “semi-invariant” w.r.t. scaling:

$$\Phi(\mathcal{Q}[X]) = -\ln \text{Det}(QXQ) = -\ln \text{Det}(X) - 2\ln \text{Det}(Q) = \Phi(X) + \text{const}(Q).$$

Now, a point on the primal central path of the problem $(\widehat{\mathcal{P}})$ associated with path parameter μ , let this point be temporarily denoted by $Y(\mu)$, is the unique minimizer of the aggregate

$$P_\mu(Y) = \langle Q^{-1}CQ^{-1}, Y \rangle + \mu\Phi(Y) \equiv \text{Tr}(Q^{-1}CQ^{-1}Y) + \mu\Phi(Y)$$

over the set \widehat{M}_P^+ of strictly feasible solutions of (\widehat{P}) . The latter set is exactly the image of the set \mathcal{M}_P^+ of strictly feasible solutions to (P) under the transformation Q , so that $Y(\mu)$ is the image, under the same transformation, of the point, let it be called $X(\mu)$, which minimizes the aggregate

$$\text{Tr}((Q^{-1}CQ^{-1})(QXQ)) + \mu\Phi(QXQ) = \text{Tr}(CX) + \mu\Phi(X) + \text{const}(Q)$$

over the set \mathcal{M}_P^+ of strictly feasible solutions to (P) . We see that $X(\mu)$ is exactly the point $X_*(\mu)$ on the primal central path associated with problem (P) . Thus, the point $Y(\mu)$ of the primal central path associated with (\widehat{P}) is nothing but $\widehat{X}_*(t) = QX_*(t)Q$. Similarly, the point of the central path associated with the problem (\widehat{D}) is exactly $\widehat{S}_*(t) = Q^{-1}S_*(t)Q^{-1}$.

- the neighbourhood of the primal-dual central path

$$\mathcal{N}_\kappa = \{(X \in \mathcal{M}_P^+, s \in \mathcal{M}_D^+) : \text{dist}((X, S), Z_*(\text{Tr}(XS)))\}$$

associated with the pair of problems (P) , (D) . As you can guess, the image of \mathcal{N}_κ is exactly the neighbourhood $\overline{\mathcal{N}}_\kappa$ of the primal-dual central path $\overline{Z}(\cdot)$ of (\widehat{P}) , (\widehat{D}) .

The latter fact is immediate: for a pair (X, S) of strictly feasible primal and dual solutions to (P) , (D) , and a $\mu > 0$ we have (see (7.2.11)):

$$\begin{aligned} & \text{dist}^2((\widehat{X}, \widehat{S}), \overline{Z}_*(\mu)) \\ &= \text{Tr}([QXQ](\mu^{-1}Q^{-1}SQ^{-1} - [QXQ]^{-1})[QXQ](\mu^{-1}Q^{-1}SQ^{-1} - [QXQ]^{-1})) \\ &= \text{Tr}(QX(\mu^{-1}S - X^{-1})X(\mu^{-1}S - X^{-1})Q^{-1}) \\ &= \text{Tr}(X(\mu^{-1}S - X^{-1})X(\mu^{-1}S - X^{-1})) \\ &= \{\text{dist}\}^2((X, S), Z_*(\mu)) \end{aligned}$$

and

$$\text{Tr}(\widehat{X}\widehat{S}) = \text{Tr}([QXQ][Q^{-1}SQ^{-1}]) = \text{Tr}(QXSQ^{-1}) = \text{Tr}(XS).$$

Proof of Theorem 7.2.2. ¹⁰. Observe, first (this observation is crucial!) that it suffices to prove our Theorem in the particular case when \bar{X}, \bar{S} commute with each other and $Q = I$. Indeed, it is immediately seen that the updating (U) can be represented as follows:

1. We first scale by Q the “input data” of (U) – the primal-dual pair of problems (P) , (D) and the strictly feasible pair \bar{X}, \bar{S} of primal and dual solutions to these problems, as explained in section “Scaling”. Note that the resulting entities – a pair of primal-dual problems and a strictly feasible pair of primal-dual solutions to these problems – are linked with each other exactly in the same fashion as the original entities, due to scaling invariance of the duality gap and the neighbourhood \mathcal{N}_κ . In addition, the scaled primal and dual solutions commute;
2. We apply to the “scaled input data” yielded by the previous step the updating (\widehat{U}) completely similar to (U), but using the unit matrix in the role of Q ;
3. We “scale back” the result of the previous step, i.e., subject this result to the scaling associated with Q^{-1} , thus obtaining the updated iterate (X_+, S_+) .

Given that the second step of this procedure preserves primal-dual strict feasibility, w.r.t. the scaled primal-dual pair of problems, of the iterate and keeps the iterate in the neighbourhood \mathcal{N}_κ of the corresponding central path, we could use once again the “scaling invariance” reasoning to assert that the result (X_+, S_+) of (U) is well-defined, is strictly feasible for (\mathcal{P}) , (\mathcal{D}) and is close to the original central path, as claimed in the Theorem. Thus, all we need is to justify the above “Given”, and this is exactly the same as to prove the theorem in the particular case of $Q = I$ and commuting \bar{X} , \bar{S} . In the rest of the proof we assume that $Q = I$ and that the matrices \bar{X} , \bar{S} commute with each other. Due to the latter property, \bar{X} , \bar{S} are diagonal in a properly chosen orthonormal basis, meaning that there exists a block-diagonal, with block-diagonal structure ν , orthogonal matrix U such that $U\bar{X}U^T$ and $U\bar{S}U^T$ are diagonal. Representing all matrices from \mathbf{S}^ν in this basis (i.e., passing from a matrix A to the matrix UAU^T), we can reduce the situation to the case when \bar{X} and \bar{S} are diagonal. Thus, we may (and do) assume in the sequel that \bar{X} and \bar{S} are diagonal, with diagonal entries x_i, s_i , $i = 1, \dots, k$, respectively, and that $Q = I$. Finally, to simplify notation, we write μ, X, S instead of $\bar{\mu}, \bar{X}, \bar{S}$, respectively.

2^0 . Our situation and goals now are as follows. We are given affine planes $\mathcal{L}_P - B$, $\mathcal{L}_D = \mathcal{L}_P^\perp$ in \mathbf{S}^ν and two positive definite diagonal matrices $X = \text{Diag}(\{x_i\}) \in \mathcal{L}_P - B$, $S = \text{Diag}(\{s_i\}) \in \mathcal{L}_D^\perp + C$. We set

$$\mu = n^{-1} \text{Tr}(XS)$$

and know that

$$\|\mu^{-1}X^{1/2}SX^{1/2} - I\|_{\text{Fr}} \leq \kappa.$$

We further set

$$\mu_+ = (1 - \chi n^{-1/2})\mu \quad (7.2.29)$$

and consider the system of equations w.r.t. unknown symmetric matrices $\Delta X, \Delta S$:

$$\begin{aligned} (a) \quad & \Delta X \in \mathcal{L}_P \\ (b) \quad & \Delta S \in \mathcal{L}_D = \mathcal{L}_P^\perp \\ (c) \quad & \Delta XS + X\Delta S + \Delta SX + S\Delta X = 2\mu_+I - 2XS \end{aligned} \quad (7.2.30)$$

We should prove that the system has a unique solution, and for this solution the matrices

$$X_+ = X + \Delta X, \quad S_+ = S + \Delta S$$

are

- (i) positive definite,
- (ii) belong, respectively, to $\mathcal{L}_P - B$, $\mathcal{L}_P^\perp + C$ and satisfy the relation

$$\text{Tr}(X_+S_+) = \mu_+n; \quad (7.2.31)$$

- (iii) satisfy the relation

$$\Omega \equiv \|\mu_+^{-1}X_+^{1/2}S_+X_+^{1/2} - I\|_{\text{Fr}} \leq \kappa. \quad (7.2.32)$$

Observe that the situation can be reduced to the one with $\mu = 1$. Indeed, let us pass from the matrices $X, S, \Delta X, \Delta S, X_+, S_+$ to $X, S' = \mu^{-1}S, \Delta X, \Delta S' = \mu^{-1}\Delta S, X_+, S'_+ = \mu^{-1}S_+$. Now the “we are given” part of our situation becomes as follows: we are given two diagonal positive definite matrices X, S' such that $X \in \mathcal{L}_P - B$, $S' \in \mathcal{L}_P^\perp + C'$, $C' = \mu^{-1}C$,

$$\text{Tr}(XS') = n \times 1$$

and

$$\|X^{1/2}S'X^{1/2} - I\|_{\text{Fr}} = \|\mu^{-1}X^{1/2}SX^{1/2} - I\|_{\text{Fr}} \leq \kappa.$$

The “we should prove” part becomes: to verify that the system of equations

$$\begin{aligned} (a) \quad & \Delta X \in \mathcal{L}_P \\ (b) \quad & \Delta S' \in \mathcal{L}_P^\perp \\ (c) \quad & \Delta XS' + X\Delta S' + \Delta S'X + S'\Delta X = 2(1 - \chi n^{-1/2})I - 2XS' \end{aligned}$$

has a unique solution and that the matrices $X_+ = X + \Delta X$, $S'_+ = S' + \Delta S'_+$ are positive definite, are contained in $\mathcal{L}_P - B$, respectively, $\mathcal{L}_P^\perp + C'$ and satisfy the relations

$$\text{Tr}(X_+S'_+) = \frac{\mu_+}{\mu} = 1 - \chi n^{-1/2}$$

and

$$\|(1 - \chi n^{-1/2})^{-1}X_+^{1/2}S'_+X_+^{1/2} - I\|_{\text{Fr}} \leq \kappa.$$

Thus, the general situation indeed can be reduced to the one with $\mu = 1$, $\mu_+ = 1 - \chi n^{-1/2}$, and we loose nothing assuming, in addition to what was already postulated, that

$$\mu \equiv n^{-1} \text{Tr}(XS) = 1, \quad \mu_+ = 1 - \chi n^{-1/2},$$

whence

$$[\text{Tr}(XS) =] \quad \sum_{i=1}^k x_i s_i = k \quad (7.2.33)$$

and

$$[\|\mu^{-1}X^{1/2}SX^{1/2} - I\|_{\text{Fr}}^2 \equiv] \quad \sum_{i=1}^n (x_i s_i - 1)^2 \leq \kappa^2. \quad (7.2.34)$$

3⁰. We start with proving that (7.2.30) indeed has a unique solution. It is convenient to pass in (7.2.30) from the unknowns ΔX , ΔS to the unknowns

$$\begin{aligned} \delta X = X^{-1/2}\Delta X X^{-1/2} & \Leftrightarrow \Delta X = X^{1/2}\delta X X^{1/2}, \\ \delta S = X^{1/2}\Delta S X^{1/2} & \Leftrightarrow \Delta S = X^{-1/2}\delta S X^{-1/2}. \end{aligned} \quad (7.2.35)$$

With respect to the new unknowns, (7.2.30) becomes

$$\begin{aligned} (a) \quad & X^{1/2}\delta X X^{1/2} \in \mathcal{L}_P, \\ (b) \quad & X^{-1/2}\delta S X^{-1/2} \in \mathcal{L}_P^\perp, \\ (c) \quad & X^{1/2}\delta X X^{1/2}S + X^{1/2}\delta S X^{-1/2} + X^{-1/2}\delta S X^{1/2} + S X^{1/2}\delta X X^{1/2} = 2\mu_+ I - 2XS \\ & \quad \quad \quad \Downarrow \\ (d) \quad & L(\delta X, \delta S) \equiv \left[\underbrace{\sqrt{x_i x_j}(s_i + s_j)}_{\phi_{ij}} (\delta X)_{ij} + \left(\underbrace{\sqrt{\frac{x_i}{x_j}} + \sqrt{\frac{x_j}{x_i}}}_{\psi_{ij}} \right) (\delta S)_{ij} \right]_{i,j=1}^n \\ & \quad \quad \quad = 2 [(\mu_+ - x_i s_i) \delta_{ij}]_{i,j=1}^n, \end{aligned} \quad (7.2.36)$$

where $\delta_{ij} = \begin{cases} 0, & i \neq j \\ 1, & i = j \end{cases}$ are the Kronecker symbols.

We first claim that (7.2.36), regarded as a system with unknown *symmetric* matrices $\delta X, \delta S$ has a unique solution. Observe that (7.2.36) is a system with $2 \dim \mathbf{S}' \equiv 2K$ scalar unknowns and $2K$ scalar linear equations. Indeed, (7.2.36.a) is a system of $K' \equiv K - \dim \mathcal{L}_P$ linear equations, (7.2.36.b) is a system of $K'' = K - \dim \mathcal{L}_P^\perp = \dim \mathcal{L}_P$ linear equations, and (7.2.36.c) has K equations, so that the total # of linear equations in our system is $K' + K'' + K = (K - \dim \mathcal{L}_P) + \dim \mathcal{L}_P + K = 2K$. Now, to verify that the *square* system of linear equations (7.2.36) has exactly one solution, it suffices to prove that the homogeneous system

$$X^{1/2} \delta X X^{1/2} \in \mathcal{L}, \quad X^{-1/2} \delta S X^{-1/2} \in \mathcal{L}^\perp, \quad L(\delta X, \delta S) = 0$$

has only trivial solution. Let $(\delta X, \delta S)$ be a solution to the homogeneous system. Relation $L(\delta X, \Delta S) = 0$ means that

$$(\delta X)_{ij} = -\frac{\psi_{ij}}{\phi_{ij}} (\delta S)_{ij}, \quad (7.2.37)$$

whence

$$\text{Tr}(\delta X \delta S) = -\sum_{i,j} \frac{\psi_{ij}}{\phi_{ij}} (\Delta S)_{ij}^2. \quad (7.2.38)$$

Representing $\delta X, \delta S$ via $\Delta X, \Delta S$ according to (7.2.35), we get

$$\text{Tr}(\delta X \delta S) = \text{Tr}(X^{-1/2} \Delta X X^{-1/2} X^{1/2} \Delta S X^{1/2}) = \text{Tr}(X^{-1/2} \Delta X \Delta S X^{1/2}) = \text{Tr}(\Delta X \Delta S),$$

and the latter quantity is 0 due to $\Delta X = X^{1/2} \delta X X^{1/2} \in \mathcal{L}_P$ and $\Delta S = X^{-1/2} \delta S X^{-1/2} \in \mathcal{L}_P^\perp$. Thus, the left hand side in (7.2.38) is 0; since $\phi_{ij} > 0$, $\psi_{ij} > 0$, (7.2.38) implies that $\delta S = 0$. But then $\delta X = 0$ in view of (7.2.37). Thus, the homogeneous version of (7.2.36) has the trivial solution only, so that (7.2.36) is solvable with a unique solution.

4⁰. Let $\delta X, \delta S$ be the unique solution to (7.2.36), and let $\Delta X, \Delta S$ be linked to $\delta X, \delta S$ according to (7.2.35). Our local goal is to bound from above the Frobenius norms of δX and δS .

From (7.2.36.c) it follows (cf. derivation of (7.2.38)) that

$$\begin{aligned} (a) \quad (\delta X)_{ij} &= -\frac{\psi_{ij}}{\phi_{ij}} (\delta S)_{ij} + 2 \frac{\mu_+ - x_i s_i}{\phi_{ii}} \delta_{ij}, \quad i, j = 1, \dots, n; \\ (b) \quad (\delta S)_{ij} &= -\frac{\phi_{ij}}{\psi_{ij}} (\delta X)_{ij} + 2 \frac{\mu_+ - x_i s_i}{\psi_{ii}} \delta_{ij}, \quad i, j = 1, \dots, n. \end{aligned} \quad (7.2.39)$$

Same as in the concluding part of 3⁰, relations (7.2.36.a – b) imply that

$$\text{Tr}(\Delta X \Delta S) = \text{Tr}(\delta X \delta S) = \sum_{i,j} (\delta X)_{ij} (\delta S)_{ij} = 0. \quad (7.2.40)$$

Multiplying (7.2.39.a) by $(\delta S)_{ij}$ and taking sum over i, j , we get, in view of (7.2.40), the relation

$$\sum_{i,j} \frac{\psi_{ij}}{\phi_{ij}} (\delta S)_{ij}^2 = 2 \sum_i \frac{\mu_+ - x_i s_i}{\phi_{ii}} (\delta S)_{ii}; \quad (7.2.41)$$

by “symmetric” reasoning, we get

$$\sum_{i,j} \frac{\phi_{ij}}{\psi_{ij}} (\delta X)_{ij}^2 = 2 \sum_i \frac{\mu_+ - x_i s_i}{\psi_{ii}} (\delta X)_{ii}. \quad (7.2.42)$$

Now let

$$\theta_i = x_i s_i, \quad (7.2.43)$$

so that in view of (7.2.33) and (7.2.34) one has

$$\begin{aligned} (a) \quad & \sum_i \theta_i = n, \\ (b) \quad & \sum_i (\theta_i - 1)^2 \leq \kappa^2. \end{aligned} \quad (7.2.44)$$

Observe that

$$\phi_{ij} = \sqrt{x_i x_j} (s_i + s_j) = \sqrt{x_i x_j} \left(\frac{\theta_i}{x_i} + \frac{\theta_j}{x_j} \right) = \theta_j \sqrt{\frac{x_i}{x_j}} + \theta_i \sqrt{\frac{x_j}{x_i}}.$$

Thus,

$$\begin{aligned} \phi_{ij} &= \theta_j \sqrt{\frac{x_i}{x_j}} + \theta_i \sqrt{\frac{x_j}{x_i}}, \\ \psi_{ij} &= \sqrt{\frac{x_i}{x_j}} + \sqrt{\frac{x_j}{x_i}}, \end{aligned} \quad (7.2.45)$$

since $1 - \kappa \leq \theta_i \leq 1 + \kappa$ by (7.2.44.b), we get

$$1 - \kappa \leq \frac{\phi_{ij}}{\psi_{ij}} \leq 1 + \kappa. \quad (7.2.46)$$

By the geometric-arithmetic mean inequality we have $\psi_{ij} \geq 2$, whence in view of (7.2.46)

$$\phi_{ij} \geq (1 - \kappa) \psi_{ij} \geq 2(1 - \kappa) \quad \forall i, j. \quad (7.2.47)$$

We now have

$$\begin{aligned} (1 - \kappa) \sum_{i,j} (\delta X)_{ij}^2 &\leq \sum_{i,j} \frac{\phi_{ij}}{\psi_{ij}} (\delta X)_{ij}^2 && [\text{see (7.2.46)}] \\ &\leq 2 \sum_i \frac{\mu_+ - x_i s_i}{\psi_{ii}} (\delta X)_{ii} && [\text{see (7.2.42)}] \\ &\leq 2 \sqrt{\sum_i (\mu_+ - x_i s_i)^2} \sqrt{\sum_i \psi_{ii}^{-2} (\delta X)_{ii}^2} \\ &\leq \sqrt{\sum_i ((1 - \theta_i)^2 - 2\chi n^{-1/2}(1 - \theta_i) + \chi^2 n^{-1})} \sqrt{\sum_{i,j} (\delta X)_{ij}^2} && [\text{see (7.2.47)}] \\ &\leq \sqrt{\chi^2 + \sum_i (1 - \theta_i)^2} \sqrt{\sum_{i,j} (\delta X)_{ij}^2} && [\text{since } \sum_i (1 - \theta_i) = 0 \text{ by (7.2.44.a)}] \\ &\leq \sqrt{\chi^2 + \kappa^2} \sqrt{\sum_{i,j} (\delta X)_{ij}^2} && [\text{see (7.2.44.b)}] \end{aligned}$$

and from the resulting inequality it follows that

$$\|\delta X\|_{\text{Fr}} \leq \rho \equiv \frac{\sqrt{\chi^2 + \kappa^2}}{1 - \kappa}. \quad (7.2.48)$$

Similarly,

$$\begin{aligned}
(1 + \kappa)^{-1} \sum_{i,j} (\delta S)_{ij}^2 &\leq \sum_{i,j} \frac{\psi_{ij}}{\phi_{ij}} (\delta S)_{ij}^2 \\
&\quad [\text{see (7.2.46)}] \\
&\leq 2 \sum_i \frac{\mu_+ - x_i s_i}{\phi_{ii}} (\delta S)_{ii} \\
&\quad [\text{see (7.2.41)}] \\
&\leq 2 \sqrt{\sum_i (\mu_+ - x_i s_i)^2} \sqrt{\sum_i \phi_{ii}^{-2} (\delta S)_{ii}^2} \\
&\leq (1 - \kappa)^{-1} \sqrt{\sum_i (\mu_+ - \theta_i)^2} \sqrt{\sum_{i,j} (\delta S)_{ij}^2} \\
&\quad [\text{see (7.2.47)}] \\
&\leq (1 - \kappa)^{-1} \sqrt{\chi^2 + \kappa^2} \sqrt{\sum_{i,j} (\delta S)_{ij}^2} \\
&\quad [\text{same as above}]
\end{aligned}$$

and from the resulting inequality it follows that

$$\|\delta S\|_{\text{Fr}} \leq \frac{(1 + \kappa) \sqrt{\chi^2 + \kappa^2}}{1 - \kappa} = (1 + \kappa) \rho. \quad (7.2.49)$$

5⁰. We are ready to prove 2⁰.(i-ii). We have

$$X_+ = X + \Delta X = X^{1/2} (I + \delta X) X^{1/2},$$

and the matrix $I + \delta X$ is positive definite due to (7.2.48) (indeed, the right hand side in (7.2.48) is $\rho \leq 1$, whence the Frobenius norm (and therefore - the maximum of moduli of eigenvalues) of δX is less than 1). Note that by the just indicated reasons $I + \delta X \preceq (1 + \rho)I$, whence

$$X_+ \preceq (1 + \rho)X. \quad (7.2.50)$$

Similarly, the matrix

$$S_+ = S + \Delta S = X^{-1/2} (X^{1/2} S X^{1/2} + \delta S) X^{-1/2}$$

is positive definite. Indeed, the eigenvalues of the matrix $X^{1/2} S X^{1/2}$ are $\geq \min_i \theta_i \geq 1 - \kappa$, while the moduli of eigenvalues of δS , by (7.2.49), do not exceed $\frac{(1 + \kappa) \sqrt{\chi^2 + \kappa^2}}{1 - \kappa} < 1 - \kappa$. Thus, the matrix $X^{1/2} S X^{1/2} + \delta S$ is positive definite, whence S_+ also is so. We have proved 2⁰.(i).

2⁰.(ii) is easy to verify. First, by (7.2.36), we have $\Delta X \in \mathcal{L}$, $\Delta S \in \mathcal{L}^\perp$, and since $X \in \mathcal{L} - B$, $S \in \mathcal{L}^\perp + C$, we have $X_+ \in \mathcal{L} - B$, $S_+ \in \mathcal{L}^\perp + C$. Second, we have

$$\begin{aligned}
\text{Tr}(X_+ S_+) &= \text{Tr}(X S + X \Delta S + \Delta X S + \Delta X \Delta S) \\
&= \text{Tr}(X S + X \Delta S + \Delta X S) \\
&\quad [\text{since } \text{Tr}(\Delta X \Delta S) = 0 \text{ due to } \Delta X \in \mathcal{L}, \Delta S \in \mathcal{L}^\perp] \\
&= \mu_+ n \\
&\quad [\text{take the trace of both sides in (7.2.30.c)}]
\end{aligned}$$

2⁰.(ii) is proved.

6⁰. It remains to verify 2⁰.(iii). We should bound from above the quantity

$$\Omega = \|\mu_+^{-1} X_+^{1/2} S_+ X_+^{1/2} - I\|_{\text{Fr}} = \|X_+^{1/2} (\mu_+^{-1} S_+ - X_+^{-1}) X_+^{1/2}\|_{\text{Fr}},$$

and our plan is first to bound from above the “close” quantity

$$\begin{aligned}\widehat{\Omega} &= \|X^{1/2}(\mu_+^{-1}S_+ - X_+^{-1})X^{1/2}\|_{\text{Fr}} = \mu_+^{-1}\|Z\|_{\text{Fr}}, \\ Z &= X^{1/2}(S_+ - \mu_+X_+^{-1})X^{1/2},\end{aligned}\tag{7.2.51}$$

and then to bound Ω in terms of $\widehat{\Omega}$.

6⁰.1. *Bounding $\widehat{\Omega}$.* We have

$$\begin{aligned}Z &= X^{1/2}(S_+ - \mu_+X_+^{-1})X^{1/2} \\ &= X^{1/2}(S + \Delta S)X^{1/2} - \mu_+X^{1/2}[X + \Delta X]^{-1}X^{1/2} \\ &= XS + \delta S - \mu_+X^{1/2}[X^{1/2}(I + \delta X)X^{1/2}]^{-1}X^{1/2} \\ &\hspace{25em}[\text{see (7.2.35)}] \\ &= XS + \delta S - \mu_+(I + \delta X)^{-1} \\ &= XS + \delta S - \mu_+(I - \delta X) - \mu_+[(I + \delta X)^{-1} - I + \delta X] \\ &= \underbrace{XS + \delta S + \delta X - \mu_+I}_{Z^1} + \underbrace{(\mu_+ - 1)\delta X}_{Z^2} + \underbrace{\mu_+[I - \delta X - (I + \delta X)^{-1}]}_{Z^3},\end{aligned}$$

so that

$$\|Z\|_{\text{Fr}} \leq \|Z^1\|_{\text{Fr}} + \|Z^2\|_{\text{Fr}} + \|Z^3\|_{\text{Fr}}.\tag{7.2.52}$$

We are about to bound separately all 3 terms in the right hand side of the latter inequality.

Bounding $\|Z^2\|_{\text{Fr}}$: We have

$$\|Z^2\|_{\text{Fr}} = |\mu_+ - 1|\|\delta X\|_{\text{Fr}} \leq \chi n^{-1/2}\rho\tag{7.2.53}$$

(see (7.2.48) and take into account that $\mu_+ - 1 = -\chi n^{-1/2}$).

Bounding $\|Z^3\|_{\text{Fr}}$: Let λ_i be the eigenvalues of δX . We have

$$\begin{aligned}\|Z^3\|_{\text{Fr}} &= \|\mu_+[(I + \delta X)^{-1} - I + \delta X]\|_{\text{Fr}} \\ &\leq \|(I + \delta X)^{-1} - I + \delta X\|_{\text{Fr}} \\ &\hspace{15em}[\text{since } |\mu_+| \leq 1] \\ &= \sqrt{\sum_i \left(\frac{1}{1+\lambda_i} - 1 + \lambda_i\right)^2} \\ &\hspace{2em}[\text{pass to the orthonormal eigenbasis of } \delta X] \\ &= \sqrt{\sum_i \frac{\lambda_i^4}{(1+\lambda_i)^2}} \\ &\leq \sqrt{\sum_i \frac{\rho^2 \lambda_i^2}{(1-\rho)^2}} \\ &\hspace{2em}[\text{see (7.2.48) and note that } \sum_i \lambda_i^2 = \|\delta X\|_{\text{Fr}}^2 \leq \rho^2] \\ &\leq \frac{\rho^2}{1-\rho}\end{aligned}\tag{7.2.54}$$

Bounding $\|Z^1\|_{\text{Fr}}$: This is a bit more involving. We have

$$\begin{aligned}Z_{ij}^1 &= (XS)_{ij} + (\delta S)_{ij} + (\delta X)_{ij} - \mu_+\delta_{ij} \\ &= (\delta X)_{ij} + (\delta S)_{ij} + (x_i s_i - \mu_+)\delta_{ij} \\ &= (\delta X)_{ij} \left[1 - \frac{\phi_{ij}}{\psi_{ij}}\right] + \left[2\frac{\mu_+ - x_i s_i}{\psi_{ii}} + x_i s_i - \mu_+\right] \delta_{ij} \\ &\hspace{15em}[\text{we have used (7.2.39.b)}] \\ &= (\delta X)_{ij} \left[1 - \frac{\phi_{ij}}{\psi_{ij}}\right] \\ &\hspace{15em}[\text{since } \psi_{ii} = 2, \text{ see (7.2.45)}]\end{aligned}$$

whence, in view of (7.2.46),

$$|Z_{ij}^1| \leq \left| 1 - \frac{1}{1-\kappa} \right| |(\delta X)_{ij}| = \frac{\kappa}{1-\kappa} |(\delta X)_{ij}|,$$

so that

$$\|Z^1\|_{\text{Fr}} \leq \frac{\kappa}{1-\kappa} \|\delta X\|_{\text{Fr}} \leq \frac{\kappa}{1-\kappa} \rho \quad (7.2.55)$$

(the concluding inequality is given by (7.2.48)).

Assembling (7.2.53), (7.2.54), (7.2.55) and (7.2.52), we come to

$$\|Z\|_{\text{Fr}} \leq \rho \left[\frac{\chi}{\sqrt{n}} + \frac{\rho}{1-\rho} + \frac{\kappa}{1-\kappa} \right],$$

whence, by (7.2.51),

$$\widehat{\Omega} \leq \frac{\rho}{1-\chi n^{-1/2}} \left[\frac{\chi}{\sqrt{n}} + \frac{\rho}{1-\rho} + \frac{\kappa}{1-\kappa} \right]. \quad (7.2.56)$$

6⁰.2. *Bounding Ω .* We have

$$\begin{aligned} \Omega^2 &= \|\mu_+^{-1} X_+^{1/2} S_+ X_+^{1/2} - I\|_{\text{Fr}}^2 \\ &= \|X_+^{1/2} \underbrace{[\mu_+^{-1} S_+ - X_+^{-1}]}_{\Theta = \Theta^T} X_+^{1/2}\|_{\text{Fr}}^2 \\ &= \text{Tr} \left(X_+^{1/2} \Theta X_+ \Theta X_+^{1/2} \right) \\ &\leq (1+\rho) \text{Tr} \left(X_+^{1/2} \Theta X \Theta X_+^{1/2} \right) \quad [\text{see (7.2.50)}] \\ &= (1+\rho) \text{Tr} \left(X_+^{1/2} \Theta X_+^{1/2} X_+^{1/2} \Theta X_+^{1/2} \right) \\ &= (1+\rho) \text{Tr} \left(X_+^{1/2} \Theta X_+^{1/2} X_+^{1/2} \Theta X_+^{1/2} \right) \\ &= (1+\rho) \text{Tr} \left(X_+^{1/2} \Theta X_+ \Theta X_+^{1/2} \right) \\ &\leq (1+\rho)^2 \text{Tr} \left(X_+^{1/2} \Theta X \Theta X_+^{1/2} \right) \quad [\text{the same (7.2.50)}] \\ &= (1+\rho)^2 \|X_+^{1/2} \Theta X_+^{1/2}\|_{\text{Fr}}^2 \\ &= (1+\rho)^2 \|X_+^{1/2} [\mu_+^{-1} S_+ - X_+^{-1}] X_+^{1/2}\|_{\text{Fr}}^2 \\ &= (1+\rho)^2 \widehat{\Omega}^2 \quad [\text{see (7.2.51)}] \end{aligned}$$

so that

$$\begin{aligned} \Omega &\leq (1+\rho) \widehat{\Omega} = \frac{\rho(1+\rho)}{1-\chi n^{-1/2}} \left[\frac{\chi}{\sqrt{n}} + \frac{\rho}{1-\rho} + \frac{\kappa}{1-\kappa} \right], \\ \rho &= \frac{\sqrt{\chi^2 + \kappa^2}}{1-\kappa}. \end{aligned} \quad (7.2.57)$$

(see (7.2.56) and (7.2.48)).

It is immediately seen that if $0 < \chi \leq \kappa \leq 0.1$, the right hand side in the resulting bound for Ω is $\leq \kappa$, as required in 2⁰.(iii). \square

7.2.6 How to Start Path-Tracing

So far, we have explained “how to travel along a the highway” – how to trace the primal-dual central path after we get close to it. The question which still remains open is “how to reach the highway” – how to come close to the primal-dual central path. It turns out that this can be achieved with the same path-following technique as applied to an appropriate auxiliary problem. We consider two schemes of the latter type – the first which requires a priori knowledge of a strictly feasible primal solutions, and the second which does not require such knowledge.

Tracing auxiliary path

Assume that the feasible set of (P) is bounded, and that we have in our disposal a strictly feasible solution \bar{x} to (P) . In this case we can act as follows. Let us look at the primal central path $x_*(\mu)$ in the space of original design variables:

$$x_*(\mu) = \operatorname{argmin}_x \{c^T x + \mu \Phi(\mathcal{A}x - B)\}.$$

We know that as $\mu \rightarrow +0$, this path approaches the optimal set of (P) . But what happens when $\mu \rightarrow \infty$? Rewriting the relation defining the path equivalently as

$$x_*(\mu) = \operatorname{argmin}_x \{\mu^{-1} c^T x + \Phi(\mathcal{A}x - B)\},$$

the answer becomes clear: as $\mu \rightarrow +\infty$, $x_*(\mu)$ converges to the unique minimizer x_K of the function $K(x) = \Phi(\mathcal{A}x - B)$ on $\operatorname{int} \mathcal{X}$, where \mathcal{X} is the feasible domain of (P) ; this minimizer is called the analytic center of \mathcal{X} .

The fact that x_K is well defined and unique follows immediately from the fact that $K(x)$ is a strongly convex function on the bounded domain $\operatorname{int} \mathcal{X}$ and that this function possesses the barrier property: $K(x_i) \rightarrow +\infty$ along every sequence of points $x_i \in \mathcal{X}$ converging to a boundary point of \mathcal{X} , where strong convexity of K follows from item III, section 7.2.2, and the fact that \mathcal{A} has trivial kernel).

We see that the “starting point” of $x_*(\cdot)$ – limit of the path $x_*(\mu)$ as $\mu \rightarrow \infty$ – is independent of c . On the other hand, let us look at the central path $\tilde{x}(\mu)$ associated with the objective $d^T x$, where $d = -\nabla K(\bar{x}) = \mathcal{A}^*(-\nabla \Phi(\mathcal{A}\bar{x} - B))$. Now let (P') be the problem obtained from (P) by replacing the objective with $d^T x$. Setting $D = -\nabla \Phi(\mathcal{A}\bar{x} - B)$, we see that $D \in \operatorname{int} \mathbf{S}_+^n$, meaning that the objective $\langle D, X \rangle$ in the “primal slack” reformulation (\mathcal{P}') of (P') is $\succ 0$ and thus is a strictly feasible solution to the geometric dual (\mathcal{D}') of (P') . Since (\mathcal{P}') is strictly feasible along with (P) , the primal-dual pair $(\mathcal{P}'), (\mathcal{D}')$ generates a primal-dual central path, so that $\tilde{x}(\cdot)$ is well defined. Now observe that by construction, $\nabla[d^T x + \Phi(\mathcal{A}x - B)]$ vanishes when $x = \bar{x}$, that is, we know that $\tilde{x}(1) = \bar{x}$. As a result, we can trace the primal-dual central path $\tilde{x}(\cdot)$ of $(\mathcal{P}'), (\mathcal{D}')$, since we know that the pair $(\mathcal{A}\bar{x} - B, D)$ is exactly on this path, the value of the path parameter being 1. Let us trace this path “backward in time”, that is, increasing the path parameter instead of decreasing it. It is immediately seen that the result of Theorem 7.2.2 remains intact when the updating rule (7.2.25) in (U) is replaced with $\mu_+ = (1 + \chi n^{-1/2})\mu$, that is, we can trace $\tilde{Z}(\mu)$, increasing the value of μ by absolute constant factor every $O(1)\sqrt{n}$ steps and staying all the time in the neighbourhood $\mathcal{N}_{0.09}$ of this path. It is not difficult to see that checking in this “back tracing” the auxiliary path the proximity to

the path of interest, we eventually will discover that this proximity is ≤ 0.1 . At this moment we already “are on the highway” and can switch to tracing the path of interest.

A shortcoming of the construction we have just presented is in the necessity to know an initial strictly feasible solution to (P) and to have the feasible domain of the problem bounded (otherwise the analytic center does not exist). We are about to present another scheme, where we trace *infeasible* path and approach optimality and feasibility simultaneously.

Infeasible start path-following method

Situation and goals. For the sake of a reader, we start with reiterating our assumptions and goals. We are interested to solve a SDO program

$$\min_x \{c^T x : X \equiv \mathcal{A}x - B \in \mathbf{S}_+^\nu\}. \quad (P)$$

The corresponding primal-dual pair, in its geometric form, is

$$\begin{aligned} \min_X \{ \langle C, X \rangle : X \in (\mathcal{M}_P := \mathcal{L}_P - B) \cap \mathbf{S}_+^\nu \} & \quad (\mathcal{P}) \\ \max_S \{ \langle B, S \rangle : S \in (\mathcal{M}_D := \mathcal{L}_P^\perp + C) \cap \mathbf{S}_+^\nu \} & \quad (\mathcal{D}) \\ [\mathcal{L}_P = \text{Im } \mathcal{A}, \mathcal{L}_D = \mathcal{L}_P^\perp = \text{Ker } \mathcal{A}^*, \mathcal{A}^*C = c] \end{aligned}$$

where \mathcal{A} has trivial kernel and (\mathcal{P}) , (\mathcal{D}) are strictly feasible.

To proceed, it is convenient to “normalize” the data as follows: when we shift B to, the shift belonging to \mathcal{L}_P , (\mathcal{P}) remains intact, remains unchanged, while (\mathcal{D}) is replaced with an equivalent problem (since when shifting B by a shift from along \mathcal{L}_P , the dual objective, restricted to the dual feasible plane, gets a constant additive term). Similarly, when we shift C , the shift belonging to \mathcal{L}_D , the dual problem (\mathcal{D}) remains intact, and the primal (\mathcal{P}) is replaced with an equivalent problem. Thus, we can shift B by a shift from \mathcal{L}_P and C by a shift from $\mathcal{L}_D = \mathcal{L}_P^\perp$, while not varying the primal-dual pair (\mathcal{P}) , (\mathcal{D}) (or, better to say, converting it to an equivalent primal-dual pair). With appropriate shifts of this type we can ensure that $B \in \mathcal{L}_P^\perp$ and $C \in \mathcal{L}_P$. We lose nothing when assuming that the data from the very beginning is normalized by the requirements

$$B \in \mathcal{L}_D = \mathcal{L}_P^\perp, \quad C \in \mathcal{L}_P, \quad (\text{Nrm})$$

which, in particular, implies that $\langle C, B \rangle = 0$, so that the duality gap at a pair (X, S) of primal-dual feasible solutions becomes

$$\text{DualityGap}(X, S) = \langle X, S \rangle = \langle C, X \rangle - \langle B, S \rangle; \quad (7.2.58)$$

to see it, it suffices to open parentheses in the equality

$$0 = \underbrace{\langle X + B, S - C \rangle}_{\substack{\in \mathcal{L}_P \\ \in \mathcal{L}_P^\perp}}$$

Our goal is rather ambitious:

to develop an interior point method for solving (\mathcal{P}) , (\mathcal{D}) which requires neither a priori knowledge of a primal-dual strictly feasible pair of solutions, nor a specific initialization phase.

The scheme. The construction we are about to present achieves the announced goal as follows.

1. We write down the following system of conic constraints in variables $X, S \in \mathbf{S}^\nu$ and additional scalar variables τ, σ :

$$\begin{aligned} (a) \quad & X + \tau B - P \in \mathcal{L}_P; \\ (b) \quad & S - \tau C - D \in \mathcal{L}_P^\perp; \\ (c) \quad & \langle C, X \rangle - \langle B, S \rangle + \sigma - d = 0; \\ (e) \quad & \text{Diag}\{X, S, \sigma, \tau\} \in \mathbf{S}^\nu \times \mathbf{S}^\nu \times \mathbf{R}_+ \times \mathbf{R}_+. \end{aligned} \tag{C}$$

Here $P, D \in \mathbf{S}^\nu, d \in \mathbf{R}$ are certain fixed entities which we choose in such a way that

- (i) We can easily point out a strictly feasible solution $\hat{Y} = \text{Diag}\{\hat{X}, \hat{S}, \hat{\sigma}, \hat{\tau} = 1\}$ to the system;
 - (ii) The solution set \mathcal{Y} of (C) is unbounded; moreover, whenever $Y_i = (X_i, S_i, \sigma_i, \tau_i) \in \mathcal{Y}$ is an unbounded sequence, we have $\tau_i \rightarrow \infty$.
2. Imagine that we have a mechanism which allows us to “run away to ∞ along \mathcal{Y} ”, i.e., to generate a sequence of points $Y_i = (X_i, S_i, \sigma_i, \tau_i) \in \mathcal{Y}$ such that $\|Y_i\| \equiv \sqrt{\|X_i\|_{\text{Fr}}^2 + \|S_i\|_{\text{Fr}}^2 + \sigma_i^2 + \tau_i^2} \rightarrow \infty$. In this case, by (ii) $\tau_i \rightarrow \infty, i \rightarrow \infty$. Let us define the normalizations

$$\tilde{X}_i = \tau_i^{-1} X_i, \quad \tilde{S}_i = \tau_i^{-1} S_i.$$

of X_i, S_i . Since $(X_i, S_i, \sigma_i, \tau_i)$ is a solution to (C), these normalizations satisfy the relations

$$\begin{aligned} (a) \quad & \tilde{X}_i \in (\mathcal{L}_P - B + \tau_i^{-1} P) \cap \mathbf{S}_+^\nu; \\ (b) \quad & \tilde{S}_i \in (\mathcal{L}_P^\perp + C + \tau_i^{-1} D) \cap \mathbf{K}; \\ (c) \quad & \langle C, \tilde{X}_i \rangle - \langle B, \tilde{S}_i \rangle \leq \tau_i^{-1} d. \end{aligned} \tag{C'}$$

Since $\tau_i \rightarrow \infty$, relations (C') say that as $i \rightarrow \infty$, the normalizations \tilde{X}_i, \tilde{S}_i simultaneously approach primal-dual feasibility for (P), (D) (see (C'.a-b)) and primal-dual optimality (see (C'.c) and recall that the duality gap, with our normalization $\langle C, B \rangle = 0$, is $\langle C, X \rangle - \langle B, S \rangle$).

3. The issue, of course, is how to build a mechanism which allows to run away to ∞ along \mathcal{Y} . The mechanism we intend to use is as follows. (C) can be rewritten in the generic form

$$Y \equiv \text{Diag}\{X, S, \sigma, \tau\} \in (\mathcal{E} + R) \cap \mathbf{S}_+^{\tilde{\nu}} \tag{G}$$

where

- $\tilde{\nu} = [\nu; \nu; 1; 1]$, that is, $\mathbf{S}^{\tilde{\nu}} = \mathbf{S}^\nu \times \mathbf{S}^\nu \times \mathbf{R}_+ \times \mathbf{R}_+$;
- \mathcal{E} is the linear subspace in $\mathbf{S}^{\tilde{\nu}}$ given by

$$\mathcal{E} = \left\{ \text{Diag}\{U, V, s, r\} : U + rB \in \mathcal{L}_P, V - rC \in \mathcal{L}_P^\perp, \langle C, U \rangle - \langle B, V \rangle + s = 0 \right\}$$

- • The point $R \in \mathbf{S}^{\tilde{\nu}}$ is given by

$$R = \text{Diag}\{P, D, d - \langle C, P \rangle + \langle B, D \rangle, 0\}.$$

Let

$$\hat{Y} = \text{Diag}\{\hat{X}, \hat{S}, \hat{\sigma}, \hat{\tau} = 1\}$$

be the strictly feasible solution to (G) given by 1.(i), and let

$$\tilde{C} = -\nabla\Phi(\hat{Y}).$$

Consider the auxiliary problem

$$\min_Y \left\{ \langle \tilde{C}, Y \rangle : Y \in (\mathcal{E} + R) \cap \mathbf{S}_+^{\tilde{\nu}} \right\}. \quad (\text{Aux})$$

By the origin of \tilde{C} , the point \hat{Y} belongs to the primal central path $\tilde{Y}_*(\mu)$ of this auxiliary problem:

$$\hat{Y} = \tilde{Y}_*(1).$$

Let us trace the primal central path $\tilde{Y}_*(\cdot)$, but increasing the value μ of the path parameter instead of decreasing it, thus enforcing μ to go to $+\infty$. What will happen in this process? Recall that the point $\tilde{Y}_*(\mu)$ of the primal central path of (Aux) minimizes the aggregate

$$\langle \tilde{C}, Y \rangle + \mu\Phi(Y)$$

over $Y \in \mathcal{Y}^+ = \{Y \in (\mathcal{E} + R) \cap \text{int } \mathbf{S}_+^{\tilde{\nu}}\}$. When μ is large, we, essentially, are trying to minimize over \mathcal{Y}^+ just $\Phi(Y)$. But the *log-det barrier restricted to an unbounded intersection of an affine plane and the interior of the associated semidefinite cone is not bounded below on this intersection*. Taking for the moment this fact as granted, let us look at the consequences. If we were minimizing the barrier Φ over \mathcal{Y}^+ , the minimum “would be achieved at infinity”; it is natural to guess (and this is indeed true) that when minimizing a slightly perturbed barrier, the minimum will run away to infinity as the level of perturbations goes to 0. Thus, we may expect (and again it is indeed true) that $\|\tilde{Y}_*(\mu)\|_{\text{Fr}} \rightarrow \infty$ as $\mu \rightarrow +\infty$, so that when tracing the path $\tilde{Y}(\mu)$ as $\mu \rightarrow 0$, we are achieving our goal of running away to infinity along \mathcal{Y} .

Here is the justification of the claim we took for granted. By 1.(i), \mathcal{Y} intersects $\text{int } \mathbf{S}_+^{\tilde{\nu}}$ and is unbounded; since \mathcal{Y} is a closed and unbounded convex set, it has a nonzero recessive direction H :¹⁴ $Y + tH \in \mathcal{Y}$ whenever $Y \in \mathcal{Y}$ and $t \geq 0$. Since $\mathcal{Y} \in \mathbf{S}_+^{\tilde{\nu}}$, H is a positive semidefinite matrix. Now let us look what happens to Φ on the ray $\{\hat{Y} + tH : t \geq 0\} \subset \mathcal{Y}$. The matrix \hat{Y} by assumption is positive definite, while H is positive semidefinite and nonzero. It follows that as $t \rightarrow \infty$, the eigenvalues of $\hat{Y} + tH$ are positive, remain bounded away from zero, and some of them tend to $+\infty$, meaning that $\Phi(\hat{Y} + tH) = \sum_{i=1}^{2n+2} \ln(\lambda_i(\hat{X} + tH)) \rightarrow -\infty$ as $t \rightarrow \infty$, so that Φ is not below bounded on \mathcal{Y}^+ .

Now let us implement the outlined approach.

¹⁴While we know this fact only for polyhedral sets, it is true for all closed convex sets.

Specifying P, D, d . Given the data of (P) , let us choose somehow $P, D \in \mathbf{S}^\nu$ in such a way that $P \succ B$, $D \succ -C$, $\hat{\sigma} > 0$ and set

$$d = \langle C, P - B \rangle - \langle B, D + C \rangle + \hat{\sigma}.$$

It is immediately seen that with this setup, the point

$$\hat{Y} = \text{Diag}\{\hat{X} = P - B, \hat{S} = C + D, \hat{\sigma}, \hat{\tau} = 1\} \quad (7.2.59)$$

is a strictly feasible solution to (Aux). Thus, our setup ensures 1.(i).

Verifying 1.(ii). This step is crucial:

Lemma 7.2.1 *Let (Aux') be the problem dual to (Aux). Then (Aux) , (Aux') is a strictly primal-dual feasible pair of problems, and, in addition, the feasible set \mathcal{Y} of (Aux) is unbounded.*

Proof. By construction, \hat{Y} is a strictly feasible solution to (Aux), whence (Aux) is strictly feasible. Also by construction, $\tilde{C} = -\nabla\Phi(\hat{Y}) \succ 0$, and since (Aux) is in the form of (\mathcal{P}) , \tilde{C} belongs to the feasible plane of (Aux') , meaning that \tilde{C} is a strictly feasible solution to (Aux') .

Now, (\mathcal{P}) , (\mathcal{D}) are strictly feasible, which by Conic Duality Theorem implies that both problems are solvable with equal optimal values. Let X_* be an optimal solution to (\mathcal{P}) , S_* be an optimal solution to (\mathcal{D}) , meaning that $X_* + B \in \mathcal{L}_P$ and $S_* - C \in \mathcal{L}_P^\perp$. Besides this, $0 = \text{DualityGap}(X_*, S_*) = \langle C, X_* \rangle - \langle B, S_* \rangle$ (see (7.2.58)). Now consider the direction $\Delta = \text{Diag}\{X_*, S_*, 0, 1\}$. Looking at the definition of \mathcal{E} , we see that $\Delta \in \mathcal{E}$, and since $X_* \succeq 0$, $S_* \succeq 0$, $\Delta \in \mathbf{S}_+^\nu$ as well. It follows that Δ is a recessive direction of \mathcal{Y} , and since Δ is nonzero, \mathcal{Y} is unbounded. \square

To complete the verification of 1.(ii), we need the following simple fact:

Lemma 7.2.2 *Let \bar{X} , \bar{S} be a strictly feasible pair of primal-dual solutions to (\mathcal{P}) , (\mathcal{D}) , so that by Lemma 7.1.1 there exists $\gamma \in (0, 1)$ such that*

$$\begin{aligned} \gamma \|X\|_{\text{Fr}} &\leq \langle \bar{S}, X \rangle \quad \forall X \in \mathbf{S}_+^\nu, \\ \gamma \|S\|_{\text{Fr}} &\leq \langle \bar{X}, S \rangle \quad \forall S \in \mathbf{S}_+^\nu. \end{aligned} \quad (!)$$

Then for every feasible solution $Y = \text{Diag}\{X, S, \sigma, \tau\}$ to (Aux) one has

$$\begin{aligned} \|Y\|_{\text{Fr}} &\leq \alpha\tau + \beta, \\ \alpha &= \gamma^{-1} [\langle \bar{X}, C \rangle - \langle \bar{S}, B \rangle] + 1, \\ \beta &= \gamma^{-1} [\langle \bar{X} + B, D \rangle + \langle \bar{S} - C, P \rangle + d]. \end{aligned} \quad (7.2.60)$$

Note that (7.2.60) clearly implies that whenever $Y_i = \text{Diag}\{\dots, \tau_i\} \in \mathcal{Y}$ are such that $\|Y_i\|_{\text{Fr}} \rightarrow \infty$ as $i \rightarrow \infty$, then $\tau_i \rightarrow \infty$ as $i \rightarrow \infty$ as well.

Proof of Lemma 7.2.2: Feasible solution Y to (Aux), by construction, is a feasible solution to (C). By (C.a) we have $X + \tau B - P \in \mathcal{L}_P$, whence, since $\bar{S} - C \in \mathcal{L}_P^\perp$,

$$0 = \langle X + \tau B - P, \bar{S} - C \rangle \Rightarrow \langle X, \bar{S} \rangle \leq \tau \langle B, C - \bar{S} \rangle + \langle P, \bar{S} - C \rangle + \langle C, X \rangle;$$

similarly, by (C.b) and due to $\bar{X} + B \in \mathcal{L}_P$, we have

$$0 = \langle S - \tau C - D, \bar{X} + B \rangle \Rightarrow \langle S, \bar{X} \rangle \leq \tau \langle C, \bar{X} + B \rangle + \langle D, \bar{X} + B \rangle - \langle B, S \rangle.$$

Summing up the resulting inequalities, we get

$$\begin{aligned} \langle X, \bar{S} \rangle + \langle S, \bar{X} \rangle &\leq \tau [\langle B, C - \bar{S} \rangle + \langle C, \bar{X} + B \rangle] \\ &+ \underbrace{[\langle C, X \rangle - \langle B, S \rangle]}_{\leq d - \sigma \text{ by (C.c)}} + [\langle P, \bar{S} - C \rangle + \langle D, \bar{X} + B \rangle], \end{aligned}$$

whence, taking into account that $X \succeq 0$, $S \succeq 0$ by (C.d) and invoking (!),

$$\gamma[\|X\|_{\text{Fr}} + \|S\|_{\text{Fr}}] + \sigma \leq \tau [\langle B, C - \bar{S} \rangle + \langle C, \bar{X} + B \rangle] + d + [\langle P, \bar{S} - C \rangle + \langle D, \bar{X} + B \rangle];$$

since $\sigma \geq 0$ by (C.d), (7.2.60) follows. \square

Tracing the path $\tilde{Y}_*(\mu)$ as $\mu \rightarrow +\infty$. The path $\tilde{Y}_*(\mu)$ is the primal central path of the strictly primal-dual feasible primal-dual pair of problems (Aux), (Aux') which are in the form of (\mathcal{P}) , (\mathcal{P}') . The only difference with the situation discussed in previous sections is that now we are interested to trace the path as $\mu \rightarrow +\infty$, starting the process from the point $\hat{Y} = \tilde{Y}_*(1)$ given by 1.(i), rather than to trace the path as $\mu \rightarrow +0$. It turns out that we have exactly the same possibilities to trace the path $\tilde{Y}_*(\mu)$ as the path parameter goes to $+\infty$ as when tracing the path as $\mu \rightarrow +0$; in particular, we can use short-step primal and primal-dual path-following methods with stepsize policies “opposite” to those mentioned, respectively, in Theorem 7.2.1 and Theorem 7.2.2 (“opposite” means that instead of increasing μ at each iteration in certain ratio, we increase it in exactly the same ratio). It can be straightforwardly verified that the results of Theorems 7.2.1, 7.2.2 remain valid in this new situation as well. Thus, in order to generate a triple (μ, Y, U) such that $\mu \in (1, \infty)$, Y is strictly feasible for (Aux), U is strictly feasible for the problem (Aux') dual to (Aux), and $\text{dist}((Y, U), \tilde{Z}_*(\mu)) \leq \kappa \leq 0.1$, it suffices to carry out

$$\mathcal{N}(\mu) = O(1)\sqrt{2n + 2 \ln(2\mu)}$$

steps of the path-following method; here $\tilde{Z}_*(\cdot)$ is the primal-dual central path of the primal-dual pair (Aux), (Aux'), and dist from now on is the distance to this path, as defined in (7.2.11) (the latter definition should, of course, be applied to (Aux), (Aux')). Thus, we understand what is the cost of arriving at a close-to-the-path triple (μ, Y, U) with a desired value $\mu \in (1, \infty)$ of the path parameter. Further, our original scheme explains how to convert the Y -component of such a triple into a pair X_t, S_t of approximate solutions to (\mathcal{P}) , (\mathcal{D}) :

$$X_\mu = \frac{1}{\tau[Y]} X[Y]; \quad S_\mu = \frac{1}{\tau[Y]} S[Y],$$

where

$$Y = \text{Diag}\{X[Y], S[Y], \sigma[Y], \tau[Y]\}$$

What we do *not* know for the moment is

(?) *What is the quality of the resulting pair (X_μ, S_μ) of approximate solutions to (\mathcal{P}) , (\mathcal{D}) as a function of μ ?*

Looking at (C'), we see that (?) is, essentially, the question of how rapidly the component $\tau[Y]$ of our “close-to-the-path triple (μ, Y, U) ” blows up when μ goes to ∞ . In view of the bound (7.2.60), the latter question, in turn, becomes “how large is $\|Y\|_{\text{Fr}}$ when μ is large.” The answers to all these questions will be obtained in the three steps to follows.

Step 1. We start with associating with $V \in \text{int } \mathbf{S}_+^{\tilde{\nu}}$ a norm on the space $\mathbf{S}^{\tilde{\nu}}$, specifically, the Euclidean norm

$$\|H\|_V = \|V^{-1/2}HV^{-1/2}\|_{\text{Fr}} = \sqrt{\text{Tr}([V^{-1/2}HV^{-1/2}]^2)} = \sqrt{\text{Tr}(V^{-1}HV^{-1}H)} = \sqrt{\langle H, \mathcal{H}(V)H \rangle}.$$

Lemma 7.2.3 *Let $V \in \text{int } \mathbf{S}_+^{\tilde{\nu}}$. Then the Dikin ellipsoid of V – the set*

$$E(V) = \{W \in \mathbf{S}^{\tilde{\nu}} : \|W - V\|_V \leq 1\}$$

is contained in $\mathbf{S}_+^{\tilde{\nu}}$.

Besides this, if $H \in \mathbf{S}_+^{\tilde{\nu}}$, then

$$\langle \nabla \Phi(V), -H \rangle \geq \|H\|_V. \quad (7.2.61)$$

Proof. For $W \in \mathbf{S}^{\tilde{\nu}}$ we have

$$\begin{aligned} \|W - V\|_V &= \|V^{-1/2}[W - V]V^{-1/2}\|_{\text{Fr}} = \|[V^{-1/2}WV^{-1/2} - I]\|_{\text{Fr}} \\ &= \sqrt{\sum_i [\lambda_i(V^{-1/2}WV^{-1/2}) - 1]^2} \quad 15 \end{aligned}$$

If now $\|W - V\|_V \leq 1$, then from the latter equality it follows that $\lambda_i(V^{-1/2}WV^{-1/2}) \geq 0$, that is, the matrix $V^{-1/2}WV^{-1/2}$ is positive semidefinite, whence W is so as well. We have proved the first statement of the lemma.

The verification of the second statement is immediate:

$$\begin{aligned} \langle \nabla \Phi(V), -H \rangle &= \langle V^{-1}, H \rangle = \text{Tr}(V^{-1}H) = \text{Tr}(V^{-1/2}HV^{-1/2}) = \sum_i \lambda_i(V^{-1/2}HV^{-1/2}) \\ &= \|\lambda(V^{-1/2}HV^{-1/2})\|_1, \end{aligned}$$

where the last equality is given by the fact that $\lambda(V^{-1/2}HV^{-1/2}) \geq 0$ due to $H \succeq 0$. On the other hand, $\|H\|_V = \sqrt{\text{Tr}([V^{-1/2}HV^{-1/2}]^2)} = \|\lambda(V^{-1/2}HV^{-1/2})\|_2$. Since $\|h\|_2 \leq \|h\|_1$ for all h , we conclude that $\|H\|_V \leq \langle \nabla \Phi(V), -H \rangle$. \square

Step 2. We have the following

Lemma 7.2.4 *Let (μ, Y, U) be a “close-to-the-path” triple, so that $\mu > 0$, Y is strictly feasible for (Aux), U is strictly feasible for the dual to (Aux) problem (Aux') and*

$$\text{dist}((Y, U), \tilde{Z}_*(\mu)) \leq \kappa \leq 0.1.$$

Then

$$\begin{aligned} (a) \quad & \max\{\langle -\nabla \Phi(Y), H \rangle : H \in \mathcal{E}, \|H\|_Y \leq 1\} \geq 1. \\ (b) \quad & \max\{\langle \mu^{-1}\tilde{C} + \nabla \Phi(Y), H \rangle : H \in \mathcal{E}, \|H\|_Y \leq 1\} \leq \kappa \leq 0.1. \end{aligned} \quad (7.2.62)$$

whence also

$$\max\{\langle -\mu^{-1}\tilde{C}, H \rangle : H \in \mathcal{E}, \|H\|_Y \leq 1\} \geq 0.9. \quad (7.2.63)$$

Proof. Since the feasible set \mathcal{Y} of (Aux) is unbounded, this set admits a nonzero recessive direction H ; clearly, $H \in \mathcal{E}$ and $H \succeq 0$. Multiplying H by appropriate positive real, we can ensure also that $\|H\|_Y = 1$. By Lemma 7.2.3 applied with Y in the role of V , we have $\langle -\nabla\Phi(Y), H \rangle \geq \|H\|_Y = 1$, and (7.2.62.a) follows.

To prove (7.2.62.b), note that (Aux) is in the form of (\mathcal{P}) , and the primal feasible plane in (Aux) is parallel to \mathcal{E} , whence the feasible plane in (Aux') is $\mathcal{E}^\perp + \tilde{C}$. Recalling what U is, we conclude that $U - \tilde{C} \in \mathcal{E}^\perp$, that is, whenever $H \in \mathcal{E}$, we have

$$\begin{aligned} \langle \mu^{-1}\tilde{C} + \nabla\Phi(Y), H \rangle &= \langle \mu^{-1}U - \nabla\Phi(Y), H \rangle = \langle \mu^{-1}U - Y^{-1}, H \rangle \\ &= \text{Tr}([\mu^{-1}U - Y^{-1}]H) = \text{Tr}(Y^{1/2}[\mu^{-1}U - Y^{-1}]HY^{-1/2}) \\ &= \text{Tr}([Y^{1/2}[\mu^{-1}U - Y^{-1}]Y^{1/2}] [Y^{-1/2}HY^{-1/2}]), \end{aligned}$$

whence by the Cauchy inequality

$$\begin{aligned} |\langle \mu^{-1}\tilde{C} + \nabla\Phi(Y), H \rangle| &\leq \sqrt{\text{Tr}([Y^{1/2}[\mu^{-1}U - Y^{-1}]Y^{1/2}]^2)} \sqrt{\text{Tr}([Y^{-1/2}HY^{-1/2}]^2)} \\ &= \sqrt{\text{Tr}(Y^{1/2}[\mu^{-1}U - Y^{-1}]Y[\mu^{-1}U - Y^{-1}]Y^{1/2})} \|H\|_Y \\ &= \sqrt{\text{Tr}(Y[\mu^{-1}U - Y^{-1}]Y[\mu^{-1}U - Y^{-1}])} \|H\|_Y \\ &= \text{dist}((Y, U); \tilde{Z}_*(\mu)) \|H\|_y \leq \kappa \|H\|_y \leq 0.1 \|H\|_Y. \end{aligned}$$

The resulting inequality holds true for all $H \in \mathcal{E}$, and (7.2.62.b) follows.

Relation (7.2.63) is an immediate consequence of (7.2.62). \square

Step 3. Now consider the following geometric construction. Given a triple (μ, Y, U) satisfying the premise of Lemma 7.2.4, let us denote by W^1 the intersection of the Dikin ellipsoid of \hat{Y} with the feasible plane of (Aux), and by W^μ the intersection of the Dikin ellipsoid of Y with the same feasible plane. Let us also extend the line segment $[\hat{Y}, Y]$ to the left of \hat{Y} until it crosses the boundary of W^1 at certain point P . Further, let us choose $H \in \mathcal{E}$ such that $\|H\|_Y = 1$ and

$$\langle -\mu^{-1}\tilde{C}, H \rangle \geq 0.9$$

(such an H exists in view of (7.2.63)) and set

$$M = Y + H; \quad N = \hat{Y} + \omega H, \quad \omega = \frac{\|\hat{Y} - P\|_{\text{Fr}}}{\|Y - P\|_{\text{Fr}}}.$$

The cross-section of the entities involved by the 2D plane passing through P, Y, M looks as shown on figure 7.2.

A. We claim, first, that the points P, M, N belong to the feasible set \mathcal{Y} of (Aux).

Indeed, since the direction $\hat{Y} - Y$ belongs to \mathcal{E} , P belongs to the feasible plane of (Aux), and since by construction P belongs to the Dikin ellipsoid of \hat{Y} , P belongs to $\mathbf{S}_+^{\tilde{Y}}$ by Lemma 7.2.3. Thus, P belongs to \mathcal{Y} . By similar reasons, with Y in the role of \hat{Y} , we have $M \in \mathcal{Y}$. Since N is a convex combination of P and M , $N \in \mathcal{Y}$ as well.

B. We further claim that

$$\langle \nabla\Phi(\hat{Y}), N - \hat{Y} \rangle = \mu\omega \langle -\mu^{-1}\tilde{C}, H \rangle \geq 0.9\omega\mu \quad (7.2.64)$$

Figure 7.2: The entities related to Step 3.

Indeed, the equality in (7.2.64) is evident, since by construction $\tilde{C} = \nabla\Phi(\hat{Y})$; the inequality is given by the choice of H .

C. We make the following simple and extremely important

Observation 7.2.2 *Let $X \in \text{int } \mathbf{S}_+^k$ and $W \in \mathbf{S}_+^k$. Then*

$$\langle \Phi(X), W - X \rangle \leq k.$$

Verification is immediate:

$$\langle \nabla\Phi(X), W - X \rangle = \langle X^{-1}, X - W \rangle = \text{Tr}(X^{-1}[X - W]) = \text{Tr}(I_K - X^{-1}W) = k - \langle X^{-1}, W \rangle \leq k,$$

where the concluding \leq is due to $X^{-1}, W \in \mathbf{S}_+^k$ and the fact that the latter cone is self-dual. \square

From A, B, C it follows that

$$\omega \leq \frac{2n+2}{0.9\mu}. \quad (!)$$

Now let

$$\Omega = \frac{0.9 \min_D [\|D\|_{\text{Fr}} : \|D\|_{\hat{Y}} = 1]}{2n+2}, \quad \Omega' = \max_D [\|D\|_{\text{Fr}} : \|D - \hat{Y}\|_{\hat{Y}} = 1].$$

Observe that Ω and Ω' are positive quantities depending on our “starting point” \hat{Y} and completely independent of μ . The role of these quantities in our context is clear from the following

Observation 7.2.3 *Under the premise of Lemma 7.2.4, one has*

$$\|Y\|_{\text{Fr}} \geq \Omega\mu - \Omega'. \quad (7.2.65)$$

Indeed, by definition of ω we have $\|Y - P\|_{\text{Fr}} = \|\hat{Y} - P\|_{\text{Fr}}\omega^{-1}$, whence, by (!), $\|Y - P\|_{\text{Fr}} \geq 0.9\mu \frac{\|\hat{Y} - P\|_{\text{Fr}}}{2n+2}$, and by the Triangle inequality,

$$\|Y\|_{\text{Fr}} \geq 0.9\mu \frac{\|\hat{Y} - P\|_{\text{Fr}}}{2n+2} - \|P\|_{\text{Fr}}.$$

It remains to note that by construction $\|\hat{Y} - P\|_{\hat{Y}} = 1$, whence $0.9 \frac{\|\hat{Y} - P\|_{\text{Fr}}}{2n+2} \geq \Omega$ and $\|P\|_{\text{Fr}} \leq \Omega'$. \square

The result. Combining Observation 7.2.3 and (7.2.60), we arrive at the following

Theorem 7.2.3 *Whenever a triple (μ, Y, U) is “close-to-the-path” (i.e., satisfies the premise of Lemma 7.2.4) and $Y = \text{Diag}\{X, S, \sigma, \tau\}$, one has*

$$\tau \geq \Theta\mu - \Theta^{-1} \quad (7.2.66)$$

with $\Theta > 0$ depending solely on the data of (P) . Consequently, when $\mu \leq 2\Theta^{-2}$, the pair $(X_\tau = \tau^{-1}X, S_\tau = \tau^{-1}S)$ satisfies the relations (cf. (C'))

$$\begin{aligned} X_\tau &\in \mathbf{S}_+^\nu \cap (\mathcal{L}_P - B + 2\mu^{-1}\Theta P) && \text{[“primal } O(1/\mu)\text{-feasibility”]} \\ S_\tau &\in \mathbf{S}_+^\nu \cap (\mathcal{L}_P^\perp + C + 2\mu^{-1}\Theta D) && \text{[“dual } O(1/\mu)\text{-feasibility”]} \\ \langle C, X_\tau \rangle - \langle B, S_\tau \rangle &\leq 2\mu^{-1}\Theta d && \text{[“} O(1/\mu)\text{-duality gap”]} \end{aligned} \quad (7.2.67)$$

Discussion. Theorem 7.2.3 says that in order to get an “ ϵ -primal-dual feasible ϵ -optimal” solution to (\mathcal{P}) , (\mathcal{D}) , it suffices to trace the primal central path of (Aux) , starting at the point \hat{Y} (path parameter equals 1) until a close-to-the-path point with path parameter $O(1/\epsilon)$ is reached, which requires $O(1)\sqrt{2n+2} \ln\left(\frac{1}{O(\epsilon)}\right)$ iterations. Thus, we arrive at a process with the same complexity characteristics as for the path-following methods described by Theorems 7.2.1 and 7.2.2; note, however, that now we have absolutely no troubles with how to start tracing the path.

At this point, a careful reader should protest: relations (7.2.67) do say that when μ is large, X_τ is nearly feasible for (\mathcal{P}) and S_τ is nearly feasible for (\mathcal{D}) ; but why do we know that X_τ, S_τ are nearly optimal for the respective problems? What pretends to ensure the latter property, is the “ $O(\mu^{-1})$ -duality gap” relation in (7.2.67), and indeed, the left hand side of this inequality looks as the duality gap, while the right hand side is $O(\mu^{-1})$. But in fact the relation

$$\text{DualityGap}(X, S) \equiv [\langle C, X \rangle - \text{Opt}(\mathcal{P})] + [\text{Opt}(\mathcal{D}) - \langle B, S \rangle] = \langle C, X \rangle - \langle B, S \rangle^{16}$$

is valid only for *primal-dual feasible pairs* (X, S) , while our X_τ, S_τ are only $O(\mu^{-1})$ -feasible.

Here is the missing element:

¹⁶⁾ In fact, in the right hand side there should also be the term $\langle C, B \rangle$; recall, however, that with our setup this term is zero.

Proposition 7.2.2 *Let the primal-dual pair of problems (\mathcal{P}) , (\mathcal{D}) be strictly primal-dual feasible and be normalized by $\langle C, B \rangle = 0$, let (X_*, S_*) be a primal-dual optimal solution to the pair, and let X, S “ ϵ -satisfy” the feasibility and optimality conditions for (\mathcal{P}) , (\mathcal{D}) , i.e.,*

$$\begin{aligned} (a) \quad & X \in \mathbf{S}_+^\nu \cap (\mathcal{L}_P - B + \Delta X), \|\Delta X\|_{\text{Fr}} \leq \epsilon, \\ (b) \quad & S \in \mathbf{S}_+^\nu \cap (\mathcal{L}_P^\perp + C + \Delta S), \|\Delta S\|_{\text{Fr}} \leq \epsilon, \\ (c) \quad & \langle C, X \rangle - \langle B, S \rangle \leq \epsilon. \end{aligned}$$

Then

$$\begin{aligned} \langle C, X \rangle - \text{Opt}(\mathcal{P}) &\leq \epsilon(1 + \|X_* + B\|_{\text{Fr}}), \\ \text{Opt}(\mathcal{D}) - \langle B, S \rangle &\leq \epsilon(1 + \|S_* - C\|_{\text{Fr}}). \end{aligned}$$

Proof. We have $S - C - \Delta S \in \mathcal{L}_P^\perp$, $X_* + B \in \mathcal{L}_P$, whence

$$\begin{aligned} 0 &= \langle S - C - \Delta S, X_* + B \rangle \\ &= \underbrace{\langle S, X_* \rangle}_{\geq 0: X_*, S \in \mathbf{S}_+^\nu = (\mathbf{S}_+^\nu)^*} - \text{Opt}(\mathcal{P}) + \langle S, B \rangle + \langle -\Delta S, X_* + B \rangle \\ \Rightarrow -\text{Opt}(\mathcal{P}) &\leq -\langle S, B \rangle + \langle \Delta S, X_* + B \rangle \leq -\langle S, B \rangle + \epsilon\|X_* + B\|_{\text{Fr}}. \end{aligned}$$

Combining the resulting inequality and (c), we get the first of the inequalities to be proved; the second of them is given by “symmetric” reasoning. \square

Appendix A

Prerequisites from Linear Algebra

Regarded as mathematical entities, the objective and the constraints in a Mathematical Programming problem are functions of several real variables; therefore before entering the Optimization Theory and Methods, we need to recall several basic notions and facts about the spaces \mathbf{R}^n where these functions live, same as about the functions themselves. The reader is supposed to know most of the facts to follow, so he/she should not be surprised by a “cooking book” style which we intend to use below.

A.1 Space \mathbf{R}^n : algebraic structure

Basically all events and constructions to be considered will take place in the *space* \mathbf{R}^n of *n-dimensional real vectors*. This space can be described as follows.

A.1.1 A point in \mathbf{R}^n

A *point* in \mathbf{R}^n (called also an *n-dimensional vector*) is an ordered collection $x = (x_1, \dots, x_n)$ of n reals, called the *coordinates*, or *components*, or *entries* of vector x ; the space \mathbf{R}^n itself is the set of all collections of this type.

A.1.2 Linear operations

\mathbf{R}^n is equipped with two *basic operations*:

- *Addition of vectors.* This operation takes on input two vectors $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ and produces from them a new vector

$$x + y = (x_1 + y_1, \dots, x_n + y_n)$$

with entries which are sums of the corresponding entries in x and in y .

- *Multiplication of vectors by reals.* This operation takes on input a real λ and an n -dimensional vector $x = (x_1, \dots, x_n)$ and produces from them a new vector

$$\lambda x = (\lambda x_1, \dots, \lambda x_n)$$

with entries which are λ times the entries of x .

The as far as addition and multiplication by reals are concerned, the arithmetic of \mathbf{R}^n inherits most of the common rules of Real Arithmetic, like $x + y = y + x$, $(x + y) + z = x + (y + z)$, $(\lambda + \mu)(x + y) = \lambda x + \mu x + \lambda y + \mu y$, $\lambda(\mu x) = (\lambda\mu)x$, etc.

A.1.3 Linear subspaces

Linear subspaces in \mathbf{R}^n are, by definition, nonempty subsets of \mathbf{R}^n which are closed with respect to addition of vectors and multiplication of vectors by reals:

$$L \subset \mathbf{R}^n \text{ is a linear subspace} \Leftrightarrow \begin{cases} L \neq \emptyset; \\ x, y \in L \Rightarrow x + y \in L; \\ x \in L, \lambda \in \mathbf{R} \Rightarrow \lambda x \in L. \end{cases}$$

A.1.3.A. Examples of linear subspaces:

1. The entire \mathbf{R}^n ;
2. The *trivial* subspace containing the single zero vector $0 = (0, \dots, 0)$ ¹⁾; (this vector/point is called also the origin)
3. The set $\{x \in \mathbf{R}^n : x_1 = 0\}$ of all vectors x with the first coordinate equal to zero.

The latter example admits a natural extension:

4. The set of all solutions to a *homogeneous* (i.e., with zero right hand side) system of linear equations

$$\left\{ x \in \mathbf{R}^n : \begin{array}{rcl} a_{11}x_1 + \dots + a_{1n}x_n & = & 0 \\ a_{21}x_1 + \dots + a_{2n}x_n & = & 0 \\ & \dots & \\ a_{m1}x_1 + \dots + a_{mn}x_n & = & 0 \end{array} \right\} \quad (\text{A.1.1})$$

always is a linear subspace in \mathbf{R}^n . This example is “generic”, that is, every linear subspace in \mathbf{R}^n is the solution set of a (finite) system of homogeneous linear equations, see Proposition A.3.6 below.

5. *Linear span of a set of vectors.* Given a nonempty set X of vectors, one can form a linear subspace $\text{Lin}(X)$, called the *linear span* of X ; this subspace consists of all vectors x which can be represented as *linear combinations* $\sum_{i=1}^N \lambda_i x_i$ of vectors from X (in $\sum_{i=1}^N \lambda_i x_i$, N is an arbitrary positive integer, λ_i are reals and x_i belong to X). Note that

$\text{Lin}(X)$ is the smallest linear subspace which contains X : if L is a linear subspace such that $L \supset X$, then $L \supset \text{Lin}(X)$ (why?).

The “linear span” example also is generic:

Every linear subspace in \mathbf{R}^n is the linear span of an appropriately chosen finite set of vectors from \mathbf{R}^n .

(see Theorem A.1.2.(i) below).

¹⁾Pay attention to the notation: we use the same symbol 0 to denote the real zero and the n -dimensional vector with all coordinates equal to zero; these two zeros are not the same, and one should understand from the context (it always is very easy) which zero is meant.

A.1.3.B. Sums and intersections of linear subspaces. Let $\{L_\alpha\}_{\alpha \in I}$ be a family (finite or infinite) of linear subspaces of \mathbf{R}^n . From this family, one can build two sets:

1. The sum $\sum_{\alpha} L_\alpha$ of the subspaces L_α which consists of all vectors which can be represented as finite sums of vectors taken each from its own subspace of the family;
2. The intersection $\bigcap_{\alpha} L_\alpha$ of the subspaces from the family.

Theorem A.1.1 Let $\{L_\alpha\}_{\alpha \in I}$ be a family of linear subspaces of \mathbf{R}^n . Then

- (i) The sum $\sum_{\alpha} L_\alpha$ of the subspaces from the family is itself a linear subspace of \mathbf{R}^n ; it is the smallest of those subspaces of \mathbf{R}^n which contain every subspace from the family;
- (ii) The intersection $\bigcap_{\alpha} L_\alpha$ of the subspaces from the family is itself a linear subspace of \mathbf{R}^n ; it is the largest of those subspaces of \mathbf{R}^n which are contained in every subspace from the family.

A.1.4 Linear independence, bases, dimensions

A collection $X = \{x^1, \dots, x^N\}$ of vectors from \mathbf{R}^n is called *linearly independent*, if no nontrivial (i.e., with at least one nonzero coefficient) linear combination of vectors from X is zero.

Example of linearly independent set: the collection of n standard basic orths $e_1 = (1, 0, \dots, 0)$, $e_2 = (0, 1, 0, \dots, 0)$, ..., $e_n = (0, \dots, 0, 1)$.

Examples of linearly dependent sets: (1) $X = \{0\}$; (2) $X = \{e_1, e_1\}$; (3) $X = \{e_1, e_2, e_1 + e_2\}$.

A collection of vectors f^1, \dots, f^m is called a *basis* in \mathbf{R}^n , if

1. The collection is linearly independent;
2. Every vector from \mathbf{R}^n is a linear combination of vectors from the collection (i.e., $\text{Lin}\{f^1, \dots, f^m\} = \mathbf{R}^n$).

Example of a basis: The collection of standard basic orths e_1, \dots, e_n is a basis in \mathbf{R}^n .

Examples of non-bases: (1) The collection $\{e_2, \dots, e_n\}$. This collection is linearly independent, but not every vector is a linear combination of the vectors from the collection; (2) The collection $\{e_1, e_1, e_2, \dots, e_n\}$. Every vector is a linear combination of vectors from the collection, but the collection is not linearly independent.

Besides the bases of the entire \mathbf{R}^n , one can speak about the bases of linear subspaces:

A collection $\{f^1, \dots, f^m\}$ of vectors is called a *basis of a linear subspace* L , if

1. The collection is linearly independent,
2. $L = \text{Lin}\{f^1, \dots, f^m\}$, i.e., all vectors f^i belong to L , and every vector from L is a linear combination of the vectors f^1, \dots, f^m .

In order to avoid trivial remarks, it makes sense to agree once for ever that

An empty set of vectors is linearly independent, and an empty linear combination of vectors $\sum_{i \in \emptyset} \lambda_i x_i$ equals to zero.

With this convention, the trivial linear subspace $L = \{0\}$ also has a basis, specifically, an empty set of vectors.

Theorem A.1.2 (i) *Let L be a linear subspace of \mathbf{R}^n . Then L admits a (finite) basis, and all bases of L are comprised of the same number of vectors; this number is called the dimension of L and is denoted by $\dim(L)$.*

We have seen that \mathbf{R}^n admits a basis comprised of n elements (the standard basic orths). From (i) it follows that every basis of \mathbf{R}^n contains exactly n vectors, and the dimension of \mathbf{R}^n is n .

(ii) *The larger is a linear subspace of \mathbf{R}^n , the larger is its dimension: if $L \subset L'$ are linear subspaces of \mathbf{R}^n , then $\dim(L) \leq \dim(L')$, and the equality takes place if and only if $L = L'$.*

We have seen that the dimension of \mathbf{R}^n is n ; according to the above convention, the trivial linear subspace $\{0\}$ of \mathbf{R}^n admits an empty basis, so that its dimension is 0. Since $\{0\} \subset L \subset \mathbf{R}^n$ for every linear subspace L of \mathbf{R}^n , it follows from (ii) that the dimension of a linear subspace in \mathbf{R}^n is an integer between 0 and n .

(iii) *Let L be a linear subspace in \mathbf{R}^n . Then*

(iii.1) *Every linearly independent subset of vectors from L can be extended to a basis of L ;*

(iii.2) *From every spanning subset X for L – i.e., a set X such that $\text{Lin}(X) = L$ – one can extract a basis of L .*

It follows from (iii) that

- every linearly independent subset of L contains at most $\dim(L)$ vectors, and if it contains exactly $\dim(L)$ vectors, it is a basis of L ;
- every spanning set for L contains at least $\dim(L)$ vectors, and if it contains exactly $\dim(L)$ vectors, it is a basis of L .

(iv) *Let L be a linear subspace in \mathbf{R}^n , and f^1, \dots, f^m be a basis in L . Then every vector $x \in L$ admits exactly one representation*

$$x = \sum_{i=1}^m \lambda_i(x) f^i$$

as a linear combination of vectors from the basis, and the mapping

$$x \mapsto (\lambda_1(x), \dots, \lambda_m(x)) : L \rightarrow \mathbf{R}^m$$

is a one-to-one mapping of L onto \mathbf{R}^m which is linear, i.e. for every $i = 1, \dots, m$ one has

$$\begin{aligned} \lambda_i(x + y) &= \lambda_i(x) + \lambda_i(y) \quad \forall (x, y \in L); \\ \lambda_i(\nu x) &= \nu \lambda_i(x) \quad \forall (x \in L, \nu \in \mathbf{R}). \end{aligned} \tag{A.1.2}$$

The reals $\lambda_i(x)$, $i = 1, \dots, m$, are called the coordinates of $x \in L$ in the basis f^1, \dots, f^m .

E.g., the coordinates of a vector $x \in \mathbf{R}^n$ in the standard basis e_1, \dots, e_n of \mathbf{R}^n – the one comprised of the standard basic orths – are exactly the entries of x .

(v) [Dimension formula] *Let L_1, L_2 be linear subspaces of \mathbf{R}^n . Then*

$$\dim(L_1 \cap L_2) + \dim(L_1 + L_2) = \dim(L_1) + \dim(L_2).$$

A.1.5 Linear mappings and matrices

A function $\mathcal{A}(x)$ (another name – *mapping*) defined on \mathbf{R}^n and taking values in \mathbf{R}^m is called *linear*, if it preserves linear operations:

$$\mathcal{A}(x + y) = \mathcal{A}(x) + \mathcal{A}(y) \quad \forall(x, y \in \mathbf{R}^n); \quad \mathcal{A}(\lambda x) = \lambda \mathcal{A}(x) \quad \forall(x \in \mathbf{R}^n, \lambda \in \mathbf{R}).$$

It is immediately seen that a linear mapping from \mathbf{R}^n to \mathbf{R}^m can be represented as multiplication by an $m \times n$ matrix:

$$\mathcal{A}(x) = Ax,$$

and this matrix is uniquely defined by the mapping: the columns A_j of A are just the images of the standard basic orths e_j under the mapping \mathcal{A} :

$$A_j = \mathcal{A}(e_j).$$

Linear mappings from \mathbf{R}^n into \mathbf{R}^m can be added to each other:

$$(\mathcal{A} + \mathcal{B})(x) = \mathcal{A}(x) + \mathcal{B}(x)$$

and multiplied by reals:

$$(\lambda \mathcal{A})(x) = \lambda \mathcal{A}(x),$$

and the results of these operations again are linear mappings from \mathbf{R}^n to \mathbf{R}^m . The addition of linear mappings and multiplication of these mappings by reals correspond to the same operations with the matrices representing the mappings: adding/multiplying by reals mappings, we add, respectively, multiply by reals the corresponding matrices.

Given two linear mappings $\mathcal{A}(x) : \mathbf{R}^n \rightarrow \mathbf{R}^m$ and $\mathcal{B}(y) : \mathbf{R}^m \rightarrow \mathbf{R}^k$, we can build their superposition

$$\mathcal{C}(x) \equiv \mathcal{B}(\mathcal{A}(x)) : \mathbf{R}^n \rightarrow \mathbf{R}^k,$$

which is again a linear mapping, now from \mathbf{R}^n to \mathbf{R}^k . In the language of matrices representing the mappings, the superposition corresponds to matrix multiplication: the $k \times n$ matrix C representing the mapping \mathcal{C} is the product of the matrices representing \mathcal{A} and \mathcal{B} :

$$\mathcal{A}(x) = Ax, \mathcal{B}(y) = By \Rightarrow \mathcal{C}(x) \equiv \mathcal{B}(\mathcal{A}(x)) = B \cdot (Ax) = (BA)x.$$

Important convention. When speaking about adding n -dimensional vectors and multiplying them by reals, it is absolutely unimportant whether we treat the vectors as the column ones, or the row ones, or write down the entries in rectangular tables, or something else. However, when matrix operations (matrix-vector multiplication, transposition, etc.) become involved, it is important whether we treat our vectors as columns, as rows, or as something else. For the sake of definiteness, *from now on we treat all vectors as column ones*, independently of how we refer to them in the text. For example, when saying for the first time what a vector is, we wrote $x = (x_1, \dots, x_n)$, which might suggest that we were speaking about row vectors. We stress that it is not the case, and the only reason for using the notation $x = (x_1, \dots, x_n)$ instead of

the “correct” one $x = \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}$ is to save space and to avoid ugly formulas like $f\left(\begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}\right)$ when

speaking about functions with vector arguments. After we have agreed that *there is no such thing as a row vector in this Lecture course*, we can use (and do use) without any harm whatever notation we want.

Exercise A.1 1. Mark in the list below those subsets of \mathbf{R}^n which are linear subspaces, find out their dimensions and point out their bases:

- (a) \mathbf{R}^n
- (b) $\{0\}$
- (c) \emptyset
- (d) $\{x \in \mathbf{R}^n : \sum_{i=1}^n ix_i = 0\}$
- (e) $\{x \in \mathbf{R}^n : \sum_{i=1}^n ix_i^2 = 0\}$
- (f) $\{x \in \mathbf{R}^n : \sum_{i=1}^n ix_i = 1\}$
- (g) $\{x \in \mathbf{R}^n : \sum_{i=1}^n ix_i^2 = 1\}$

2. It is known that L is a subspace of \mathbf{R}^n with exactly one basis. What is L ?

3. Consider the space $\mathbf{R}^{m \times n}$ of $m \times n$ matrices with real entries. As far as linear operations – addition of matrices and multiplication of matrices by reals – are concerned, this space can be treated as certain \mathbf{R}^N .

- (a) Find the dimension of $\mathbf{R}^{m \times n}$ and point out a basis in this space
- (b) In the space $\mathbf{R}^{n \times n}$ of square $n \times n$ matrices, there are two interesting subsets: the set \mathbf{S}^n of symmetric matrices $\{A = [A_{ij}] : A_{ij} = A_{ji}\}$ and the set \mathbf{J}^n of skew-symmetric matrices $\{A = [A_{ij}] : A_{ij} = -A_{ji}\}$.
 - i. Verify that both \mathbf{S}^n and \mathbf{J}^n are linear subspaces of $\mathbf{R}^{n \times n}$
 - ii. Find the dimension and point out a basis in \mathbf{S}^n
 - iii. Find the dimension and point out a basis in \mathbf{J}^n
 - iv. What is the sum of \mathbf{S}^n and \mathbf{J}^n ? What is the intersection of \mathbf{S}^n and \mathbf{J}^n ?

A.2 Space \mathbf{R}^n : Euclidean structure

So far, we were interested solely in the algebraic structure of \mathbf{R}^n , or, which is the same, in the properties of the *linear* operations (addition of vectors and multiplication of vectors by scalars) the space is endowed with. Now let us consider another structure on \mathbf{R}^n – the *standard Euclidean structure* – which allows to speak about distances, angles, convergence, etc., and thus makes the space \mathbf{R}^n a much richer mathematical entity.

A.2.1 Euclidean structure

The standard Euclidean structure on \mathbf{R}^n is given by the *standard inner product* – an operation which takes on input two vectors x, y and produces from them a real, specifically, the real

$$\langle x, y \rangle \equiv x^T y = \sum_{i=1}^n x_i y_i$$

The basic properties of the inner product are as follows:

1. [bi-linearity]: The real-valued function $\langle x, y \rangle$ of two vector arguments $x, y \in \mathbf{R}^n$ is linear with respect to every one of the arguments, the other argument being fixed:

$$\begin{aligned}\langle \lambda u + \mu v, y \rangle &= \lambda \langle u, y \rangle + \mu \langle v, y \rangle \quad \forall (u, v, y \in \mathbf{R}^n, \lambda, \mu \in \mathbf{R}) \\ \langle x, \lambda u + \mu v \rangle &= \lambda \langle x, u \rangle + \mu \langle x, v \rangle \quad \forall (x, u, v \in \mathbf{R}^n, \lambda, \mu \in \mathbf{R})\end{aligned}$$

2. [symmetry]: The function $\langle x, y \rangle$ is symmetric:

$$\langle x, y \rangle = \langle y, x \rangle \quad \forall (x, y \in \mathbf{R}^n).$$

3. [positive definiteness]: The quantity $\langle x, x \rangle$ always is nonnegative, and it is zero if and only if x is zero.

Remark A.2.1 The outlined 3 properties – bi-linearity, symmetry and positive definiteness – form a definition of an Euclidean inner product, and there are infinitely many different from each other ways to satisfy these properties; in other words, there are infinitely many different Euclidean inner products on \mathbf{R}^n . The standard inner product $\langle x, y \rangle = x^T y$ is just a particular case of this general notion. Although in the sequel we normally work with the standard inner product, the reader should remember that the facts we are about to recall are valid for all Euclidean inner products, and not only for the standard one.

The notion of an inner product underlies a number of purely algebraic constructions, in particular, those of *inner product representation of linear forms* and of *orthogonal complement*.

A.2.2 Inner product representation of linear forms on \mathbf{R}^n

A *linear form* on \mathbf{R}^n is a real-valued function $f(x)$ on \mathbf{R}^n which is additive ($f(x+y) = f(x) + f(y)$) and homogeneous ($f(\lambda x) = \lambda f(x)$)

Example of linear form: $f(x) = \sum_{i=1}^n i x_i$

Examples of non-linear functions: (1) $f(x) = x_1 + 1$; (2) $f(x) = x_1^2 - x_2^2$; (3) $f(x) = \sin(x_1)$.

When adding/multiplying by reals linear forms, we again get linear forms (scientifically speaking: “linear forms on \mathbf{R}^n form a linear space”). *Euclidean structure allows to identify linear forms on \mathbf{R}^n with vectors from \mathbf{R}^n :*

Theorem A.2.1 Let $\langle \cdot, \cdot \rangle$ be a Euclidean inner product on \mathbf{R}^n .

(i) Let $f(x)$ be a linear form on \mathbf{R}^n . Then there exists a uniquely defined vector $f \in \mathbf{R}^n$ such that the form is just the inner product with f :

$$f(x) = \langle f, x \rangle \quad \forall x$$

(ii) Vice versa, every vector $f \in \mathbf{R}^n$ defines, via the formula

$$f(x) \equiv \langle f, x \rangle,$$

a linear form on \mathbf{R}^n ;

(iii) The above one-to-one correspondence between the linear forms and vectors on \mathbf{R}^n is linear: adding linear forms (or multiplying a linear form by a real), we add (respectively, multiply by the real) the vector(s) representing the form(s).

A.2.3 Orthogonal complement

An Euclidean structure allows to associate with a linear subspace $L \subset \mathbf{R}^n$ another linear subspace L^\perp – the *orthogonal complement* (or the *annulator*) of L ; by definition, L^\perp consists of all vectors which are orthogonal to every vector from L :

$$L^\perp = \{f : \langle f, x \rangle = 0 \quad \forall x \in L\}.$$

Theorem A.2.2 (i) *Twice taken, orthogonal complement recovers the original subspace: whenever L is a linear subspace of \mathbf{R}^n , one has*

$$(L^\perp)^\perp = L;$$

(ii) *The larger is a linear subspace L , the smaller is its orthogonal complement: if $L_1 \subset L_2$ are linear subspaces of \mathbf{R}^n , then $L_1^\perp \supset L_2^\perp$*

(iii) *The intersection of a subspace and its orthogonal complement is trivial, and the sum of these subspaces is the entire \mathbf{R}^n :*

$$L \cap L^\perp = \{0\}, \quad L + L^\perp = \mathbf{R}^n.$$

Remark A.2.2 From Theorem A.2.2.(iii) and the Dimension formula (Theorem A.1.2.(v)) it follows, first, that for every subspace L in \mathbf{R}^n one has

$$\dim(L) + \dim(L^\perp) = n.$$

Second, every vector $x \in \mathbf{R}^n$ admits a unique decomposition

$$x = x_L + x_{L^\perp}$$

into a sum of two vectors: the first of them, x_L , belongs to L , and the second, x_{L^\perp} , belongs to L^\perp . This decomposition is called the *orthogonal decomposition* of x taken with respect to L, L^\perp ; x_L is called the *orthogonal projection* of x onto L , and x_{L^\perp} – the orthogonal projection of x onto the orthogonal complement of L . Both projections depend on x linearly, for example,

$$(x + y)_L = x_L + y_L, \quad (\lambda x)_L = \lambda x_L.$$

The mapping $x \mapsto x_L$ is called the *orthogonal projector* onto L .

A.2.4 Orthonormal bases

A collection of vectors f^1, \dots, f^m is called *orthonormal* w.r.t. Euclidean inner product $\langle \cdot, \cdot \rangle$, if distinct vector from the collection are orthogonal to each other:

$$i \neq j \Rightarrow \langle f^i, f^j \rangle = 0$$

and inner product of every vector f^i with itself is unit:

$$\langle f^i, f^i \rangle = 1, \quad i = 1, \dots, m.$$

Theorem A.2.3 (i) *An orthonormal collection f^1, \dots, f^m always is linearly independent and is therefore a basis of its linear span $L = \text{Lin}(f^1, \dots, f^m)$ (such a basis in a linear subspace is called orthonormal). The coordinates of a vector $x \in L$ w.r.t. an orthonormal basis f^1, \dots, f^m of L are given by explicit formulas:*

$$x = \sum_{i=1}^m \lambda_i(x) f^i \Leftrightarrow \lambda_i(x) = \langle x, f^i \rangle.$$

Example of an orthonormal basis in \mathbf{R}^n : The standard basis $\{e_1, \dots, e_n\}$ is orthonormal with respect to the standard inner product $\langle x, y \rangle = x^T y$ on \mathbf{R}^n (but is not orthonormal w.r.t. other Euclidean inner products on \mathbf{R}^n).

Proof of (i): Taking inner product of both sides in the equality

$$x = \sum_j \lambda_j(x) f^j$$

with f^i , we get

$$\begin{aligned} \langle x, f^i \rangle &= \langle \sum_j \lambda_j(x) f^j, f^i \rangle \\ &= \sum_j \lambda_j(x) \langle f^j, f^i \rangle \quad [\text{bilinearity of inner product}] \\ &= \lambda_i(x) \quad [\text{orthonormality of } \{f^i\}] \end{aligned}$$

Similar computation demonstrates that if 0 is represented as a linear combination of f^i with certain coefficients λ_i , then $\lambda_i = \langle 0, f^i \rangle = 0$, i.e., all the coefficients are zero; this means that an orthonormal system is linearly independent.

(ii) *If f^1, \dots, f^m is an orthonormal basis in a linear subspace L , then the inner product of two vectors $x, y \in L$ in the coordinates $\lambda_i(\cdot)$ w.r.t. this basis is given by the standard formula*

$$\langle x, y \rangle = \sum_{i=1}^m \lambda_i(x) \lambda_i(y).$$

Proof:

$$\begin{aligned} x &= \sum_i \lambda_i(x) f^i, \quad y = \sum_i \lambda_i(y) f^i \\ \Rightarrow \langle x, y \rangle &= \langle \sum_i \lambda_i(x) f^i, \sum_i \lambda_i(y) f^i \rangle \\ &= \sum_{i,j} \lambda_i(x) \lambda_j(y) \langle f^i, f^j \rangle \quad [\text{bilinearity of inner product}] \\ &= \sum_i \lambda_i(x) \lambda_i(y) \quad [\text{orthonormality of } \{f^i\}] \end{aligned}$$

(iii) *Every linear subspace L of \mathbf{R}^n admits an orthonormal basis; moreover, every orthonormal system f^1, \dots, f^m of vectors from L can be extended to an orthonormal basis in L .*

Important corollary: All Euclidean spaces of the same dimension are “the same”. Specifically, if L is an m -dimensional space in a space \mathbf{R}^n equipped with an Euclidean inner product $\langle \cdot, \cdot \rangle$, then there exists a one-to-one mapping $x \mapsto A(x)$ of L onto \mathbf{R}^m such that

- The mapping preserves linear operations:

$$A(x + y) = A(x) + A(y) \quad \forall (x, y \in L); \quad A(\lambda x) = \lambda A(x) \quad \forall (x \in L, \lambda \in \mathbf{R});$$

- The mapping converts the $\langle \cdot, \cdot \rangle$ inner product on L into the standard inner product on \mathbf{R}^m :

$$\langle x, y \rangle = (A(x))^T A(y) \quad \forall x, y \in L.$$

Indeed, by (iii) L admits an orthonormal basis f^1, \dots, f^m ; using (ii), one can immediately check that the mapping

$$x \mapsto A(x) = (\lambda_1(x), \dots, \lambda_m(x))$$

which maps $x \in L$ into the m -dimensional vector comprised of the coordinates of x in the basis f^1, \dots, f^m , meets all the requirements.

Proof of (iii) is given by important by its own right *Gram-Schmidt orthogonalization process* as follows. We start with an arbitrary basis h^1, \dots, h^m in L and step by step convert it into an orthonormal basis f^1, \dots, f^m . At the beginning of a step t of the construction, we already have an orthonormal collection f^1, \dots, f^{t-1} such that $\text{Lin}\{f^1, \dots, f^{t-1}\} = \text{Lin}\{h^1, \dots, h^{t-1}\}$. At a step t we

1. Build the vector

$$g^t = h^t - \sum_{j=1}^{t-1} \langle h^t, f^j \rangle f^j.$$

It is easily seen (check it!) that

- (a) One has

$$\text{Lin}\{f^1, \dots, f^{t-1}, g^t\} = \text{Lin}\{h^1, \dots, h^t\}; \quad (\text{A.2.1})$$

- (b) $g^t \neq 0$ (derive this fact from (A.2.1) and the linear independence of the collection h^1, \dots, h^m);
 - (c) g^t is orthogonal to f^1, \dots, f^{t-1}
2. Since $g^t \neq 0$, the quantity $\langle g^t, g^t \rangle$ is positive (positive definiteness of the inner product), so that the vector

$$f^t = \frac{1}{\sqrt{\langle g^t, g^t \rangle}} g^t$$

is well defined. It is immediately seen (check it!) that the collection f^1, \dots, f^t is orthonormal and

$$\text{Lin}\{f^1, \dots, f^t\} = \text{Lin}\{f^1, \dots, f^{t-1}, g^t\} = \text{Lin}\{h^1, \dots, h^t\}.$$

Step t of the orthogonalization process is completed.

After m steps of the optimization process, we end up with an orthonormal system f^1, \dots, f^m of vectors from L such that

$$\text{Lin}\{f^1, \dots, f^m\} = \text{Lin}\{h^1, \dots, h^m\} = L,$$

so that f^1, \dots, f^m is an orthonormal basis in L .

The construction can be easily modified (do it!) to extend a given orthonormal system of vectors from L to an orthonormal basis of L .

Exercise A.2 1. What is the orthogonal complement (w.r.t. the standard inner product) of the subspace $\{x \in \mathbf{R}^n : \sum_{i=1}^n x_i = 0\}$ in \mathbf{R}^n ?

2. Find an orthonormal basis (w.r.t. the standard inner product) in the linear subspace $\{x \in \mathbf{R}^n : x_1 = 0\}$ of \mathbf{R}^n

3. Let L be a linear subspace of \mathbf{R}^n , and f^1, \dots, f^m be an orthonormal basis in L . Prove that for every $x \in \mathbf{R}^n$, the orthogonal projection x_L of x onto L is given by the formula

$$x_L = \sum_{i=1}^m (x^T f^i) f^i.$$

4. Let L_1, L_2 be linear subspaces in \mathbf{R}^n . Verify the formulas

$$(L_1 + L_2)^\perp = L_1^\perp \cap L_2^\perp; \quad (L_1 \cap L_2)^\perp = L_1^\perp + L_2^\perp.$$

5. Consider the space of $m \times n$ matrices $\mathbf{R}^{m \times n}$, and let us equip it with the “standard inner product” (called the Frobenius inner product)

$$\langle A, B \rangle = \sum_{i,j} A_{ij} B_{ij}$$

(as if we were treating $m \times n$ matrices as mn -dimensional vectors, writing the entries of the matrices column by column, and then taking the standard inner product of the resulting long vectors).

- (a) Verify that in terms of matrix multiplication the Frobenius inner product can be written as

$$\langle A, B \rangle = \text{Tr}(AB^T),$$

where $\text{Tr}(C)$ is the trace (the sum of diagonal elements) of a square matrix C .

- (b) Build an orthonormal basis in the linear subspace \mathbf{S}^n of symmetric $n \times n$ matrices
 (c) What is the orthogonal complement of the subspace \mathbf{S}^n of symmetric $n \times n$ matrices in the space $\mathbf{R}^{n \times n}$ of square $n \times n$ matrices?
 (d) Find the orthogonal decomposition, w.r.t. \mathbf{S}^2 , of the matrix $\begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix}$

A.3 Affine subspaces in \mathbf{R}^n

Many of events to come will take place not in the entire \mathbf{R}^n , but in its *affine subspaces* which, geometrically, are planes of different dimensions in \mathbf{R}^n . Let us become acquainted with these subspaces.

A.3.1 Affine subspaces and affine hulls

Definition of an affine subspace. Geometrically, a linear subspace L of \mathbf{R}^n is a special plane – the one passing through the origin of the space (i.e., containing the zero vector). To get an arbitrary plane M , it suffices to subject an appropriate special plane L to a translation – to add to all points from L a fixed *shifting vector* a . This geometric intuition leads to the following

Definition A.3.1 [Affine subspace] *An affine subspace (a plane) in \mathbf{R}^n is a set of the form*

$$M = a + L = \{y = a + x \mid x \in L\}, \quad (\text{A.3.1})$$

where L is a linear subspace in \mathbf{R}^n and a is a vector from \mathbf{R}^n ²⁾.

E.g., shifting the linear subspace L comprised of vectors with zero first entry by a vector $a = (a_1, \dots, a_n)$, we get the set $M = a + L$ of all vectors x with $x_1 = a_1$; according to our terminology, this is an affine subspace.

Immediate question about the notion of an affine subspace is: what are the “degrees of freedom” in decomposition (A.3.1) – how “strict” M determines a and L ? The answer is as follows:

Proposition A.3.1 *The linear subspace L in decomposition (A.3.1) is uniquely defined by M and is the set of all differences of the vectors from M :*

$$L = M - M = \{x - y \mid x, y \in M\}. \quad (\text{A.3.2})$$

The shifting vector a is not uniquely defined by M and can be chosen as an arbitrary vector from M .

A.3.2 Intersections of affine subspaces, affine combinations and affine hulls

An immediate conclusion of Proposition A.3.1 is as follows:

Corollary A.3.1 *Let $\{M_\alpha\}$ be an arbitrary family of affine subspaces in \mathbf{R}^n , and assume that the set $M = \cap_\alpha M_\alpha$ is nonempty. Then M_α is an affine subspace.*

From Corollary A.3.1 it immediately follows that for every nonempty subset Y of \mathbf{R}^n there exists the smallest affine subspace containing Y – the intersection of all affine subspaces containing Y . This smallest affine subspace containing Y is called the *affine hull* of Y (notation: $\text{Aff}(Y)$).

All this resembles a lot the story about linear spans. Can we further extend this analogy and to get a description of the affine hull $\text{Aff}(Y)$ in terms of elements of Y similar to the one of the linear span (“linear span of X is the set of all linear combinations of vectors from X ”)? Sure we can!

Let us choose somehow a point $y_0 \in Y$, and consider the set

$$X = Y - y_0.$$

All affine subspaces containing Y should contain also y_0 and therefore, by Proposition A.3.1, can be represented as $M = y_0 + L$, L being a linear subspace. It is absolutely evident that an affine subspace $M = y_0 + L$ contains Y if and only if the subspace L contains X , and that the larger is L , the larger is M :

$$L \subset L' \Rightarrow M = y_0 + L \subset M' = y_0 + L'.$$

Thus, to find the smallest among *affine subspaces containing Y* , it suffices to find the smallest among the *linear subspaces containing X* and to translate the latter space by y_0 :

$$\text{Aff}(Y) = y_0 + \text{Lin}(X) = y_0 + \text{Lin}(Y - y_0). \quad (\text{A.3.3})$$

²⁾according to our convention on arithmetic of sets, I was supposed to write in (A.3.1) $\{a\} + L$ instead of $a + L$ – we did not define arithmetic sum of a vector and a set. Usually people ignore this difference and omit the brackets when writing down singleton sets in similar expressions: we shall write $a + L$ instead of $\{a\} + L$, $\mathbf{R}d$ instead of $\mathbf{R}\{d\}$, etc.

Now, we know what is $\text{Lin}(Y - y_0)$ – this is a set of all linear combinations of vectors from $Y - y_0$, so that a generic element of $\text{Lin}(Y - y_0)$ is

$$x = \sum_{i=1}^k \mu_i (y_i - y_0) \quad [k \text{ may depend of } x]$$

with $y_i \in Y$ and real coefficients μ_i . It follows that the generic element of $\text{Aff}(Y)$ is

$$y = y_0 + \sum_{i=1}^k \mu_i (y_i - y_0) = \sum_{i=0}^k \lambda_i y_i,$$

where

$$\lambda_0 = 1 - \sum_i \mu_i, \quad \lambda_i = \mu_i, \quad i \geq 1.$$

We see that a generic element of $\text{Aff}(Y)$ is a linear combination of vectors from Y . Note, however, that the coefficients λ_i in this combination are not completely arbitrary: their sum is equal to 1. Linear combinations of this type – with the unit sum of coefficients – have a special name – they are called affine combinations.

We have seen that every vector from $\text{Aff}(Y)$ is an affine combination of vectors of Y . Whether the inverse is true, i.e., whether $\text{Aff}(Y)$ contains all affine combinations of vectors from Y ? The answer is positive. Indeed, if

$$y = \sum_{i=1}^k \lambda_i y_i$$

is an affine combination of vectors from Y , then, using the equality $\sum_i \lambda_i = 1$, we can write it also as

$$y = y_0 + \sum_{i=1}^k \lambda_i (y_i - y_0),$$

y_0 being the “marked” vector we used in our previous reasoning, and the vector of this form, as we already know, belongs to $\text{Aff}(Y)$. Thus, we come to the following

Proposition A.3.2 [Structure of affine hull]

$$\text{Aff}(Y) = \{ \text{the set of all affine combinations of vectors from } Y \}.$$

When Y itself is an affine subspace, it, of course, coincides with its affine hull, and the above Proposition leads to the following

Corollary A.3.2 *An affine subspace M is closed with respect to taking affine combinations of its members – every combination of this type is a vector from M . Vice versa, a nonempty set which is closed with respect to taking affine combinations of its members is an affine subspace.*

A.3.3 Affinely spanning sets, affinely independent sets, affine dimension

Affine subspaces are closely related to linear subspaces, and the basic notions associated with linear subspaces have natural and useful affine analogies. Here we introduce these notions and discuss their basic properties.

Affinely spanning sets. Let $M = a + L$ be an affine subspace. We say that a subset Y of M is *affinely spanning* for M (we say also that Y spans M affinely, or that M is affinely spanned by Y), if $M = \text{Aff}(Y)$, or, which is the same due to Proposition A.3.2, if every point of M is an affine combination of points from Y . An immediate consequence of the reasoning of the previous Section is as follows:

Proposition A.3.3 *Let $M = a + L$ be an affine subspace and Y be a subset of M , and let $y_0 \in Y$. The set Y affinely spans M – $M = \text{Aff}(Y)$ – if and only if the set*

$$X = Y - y_0$$

spans the linear subspace L : $L = \text{Lin}(X)$.

Affinely independent sets. A linearly independent set x_1, \dots, x_k is a set such that no nontrivial linear combination of x_1, \dots, x_k equals to zero. An equivalent definition is given by Theorem A.1.2.(iv): x_1, \dots, x_k are linearly independent, if the coefficients in a linear combination

$$x = \sum_{i=1}^k \lambda_i x_i$$

are uniquely defined by the value x of the combination. This equivalent form reflects the essence of the matter – what we indeed need, is the uniqueness of the coefficients in expansions. Accordingly, this equivalent form is the prototype for the notion of an affinely independent set: we want to introduce this notion in such a way that the coefficients λ_i in an *affine* combination

$$y = \sum_{i=0}^k \lambda_i y_i$$

of “affinely independent” set of vectors y_0, \dots, y_k would be uniquely defined by y . Non-uniqueness would mean that

$$\sum_{i=0}^k \lambda_i y_i = \sum_{i=0}^k \lambda'_i y_i$$

for two different collections of coefficients λ_i and λ'_i with unit sums of coefficients; if it is the case, then

$$\sum_{i=0}^m (\lambda_i - \lambda'_i) y_i = 0,$$

so that y_i ’s are linearly dependent and, moreover, there exists a nontrivial zero combination of them with *zero sum of coefficients* (since $\sum_i (\lambda_i - \lambda'_i) = \sum_i \lambda_i - \sum_i \lambda'_i = 1 - 1 = 0$). Our reasoning can be inverted – if there exists a nontrivial linear combination of y_i ’s with zero sum of coefficients which is zero, then the coefficients in the representation of a vector as an affine combination of y_i ’s are not uniquely defined. Thus, in order to get uniqueness we should for sure forbid relations

$$\sum_{i=0}^k \mu_i y_i = 0$$

with nontrivial zero sum coefficients μ_i . Thus, we have motivated the following

Definition A.3.2 [Affinely independent set] *A collection y_0, \dots, y_k of n -dimensional vectors is called affinely independent, if no nontrivial linear combination of the vectors with zero sum of coefficients is zero:*

$$\sum_{i=1}^k \lambda_i y_i = 0, \sum_{i=0}^k \lambda_i = 0 \Rightarrow \lambda_0 = \lambda_1 = \dots = \lambda_k = 0.$$

With this definition, we get the result completely similar to the one of Theorem A.1.2.(iv):

Corollary A.3.3 *Let y_0, \dots, y_k be affinely independent. Then the coefficients λ_i in an affine combination*

$$y = \sum_{i=0}^k \lambda_i y_i \quad \left[\sum_i \lambda_i = 1 \right]$$

of the vectors y_0, \dots, y_k are uniquely defined by the value y of the combination.

Verification of affine independence of a collection can be immediately reduced to verification of linear independence of closely related collection:

Proposition A.3.4 *$k+1$ vectors y_0, \dots, y_k are affinely independent if and only if the k vectors $(y_1 - y_0), (y_2 - y_0), \dots, (y_k - y_0)$ are linearly independent.*

From the latter Proposition it follows, e.g., that the collection $0, e_1, \dots, e_n$ comprised of the origin and the standard basic orths is affinely independent. Note that this collection is linearly dependent (as every collection containing zero). You should definitely know the difference between the two notions of independence we deal with: linear independence means that no nontrivial linear combination of the vectors can be zero, while affine independence means that no nontrivial linear combination *from certain restricted class of them* (with zero sum of coefficients) can be zero. Therefore, there are more affinely independent sets than the linearly independent ones: a linearly independent set is for sure affinely independent, but not vice versa.

Affine bases and affine dimension. Propositions A.3.2 and A.3.3 reduce the notions of affine spanning/affine independent sets to the notions of spanning/linearly independent ones. Combined with Theorem A.1.2, they result in the following analogies of the latter two statements:

Proposition A.3.5 [Affine dimension] *Let $M = a + L$ be an affine subspace in \mathbf{R}^n . Then the following two quantities are finite integers which are equal to each other:*

- (i) *minimal # of elements in the subsets of M which affinely span M ;*
- (ii) *maximal # of elements in affine independent subsets of M .*

The common value of these two integers is by 1 more than the dimension $\dim L$ of L .

By definition, the *affine dimension* of an affine subspace $M = a + L$ is the dimension $\dim L$ of L . Thus, if M is of affine dimension k , then the minimal cardinality of sets affinely spanning M , same as the maximal cardinality of affine independent subsets of M , is $k+1$.

Theorem A.3.1 [Affine bases] *Let $M = a + L$ be an affine subspace in \mathbf{R}^n .*

A. *Let $Y \subset M$. The following three properties of Y are equivalent:*

- (i) *Y is an affine independent set which affinely spans M ;*
- (ii) *Y is affine independent and contains $1 + \dim L$ elements;*
- (iii) *Y affinely spans M and contains $1 + \dim L$ elements.*

A subset Y of M possessing the indicated equivalent to each other properties is called an affine basis of M . Affine bases in M are exactly the collections $y_0, \dots, y_{\dim L}$ such that $y_0 \in M$ and $(y_1 - y_0), \dots, (y_{\dim L} - y_0)$ is a basis in L .

B. Every affinely independent collection of vectors of M either itself is an affine basis of M , or can be extended to such a basis by adding new vectors. In particular, there exists affine basis of M .

C. Given a set Y which affinely spans M , you can always extract from this set an affine basis of M .

We already know that the standard basic orths e_1, \dots, e_n form a basis of the entire space \mathbf{R}^n . And what about affine bases in \mathbf{R}^n ? According to Theorem A.3.1.A, you can choose as such a basis a collection $e_0, e_0 + e_1, \dots, e_0 + e_n$, e_0 being an arbitrary vector.

Barycentric coordinates. Let M be an affine subspace, and let y_0, \dots, y_k be an affine basis of M . Since the basis, by definition, affinely spans M , every vector y from M is an affine combination of the vectors of the basis:

$$y = \sum_{i=0}^k \lambda_i y_i \quad \left[\sum_{i=0}^k \lambda_i = 1 \right],$$

and since the vectors of the affine basis are affinely independent, the coefficients of this combination are uniquely defined by y (Corollary A.3.3). These coefficients are called *barycentric coordinates* of y with respect to the affine basis in question. In contrast to the usual coordinates with respect to a (linear) basis, the barycentric coordinates could not be quite arbitrary: their sum should be equal to 1.

A.3.4 Dual description of linear subspaces and affine subspaces

To the moment we have introduced the notions of linear subspace and affine subspace and have presented a scheme of generating these entities: to get, e.g., a linear subspace, you start from an arbitrary nonempty set $X \subset \mathbf{R}^n$ and add to it all linear combinations of the vectors from X . When replacing linear combinations with the affine ones, you get a way to generate affine subspaces.

The just indicated way of generating linear subspaces/affine subspaces resembles the approach of a worker building a house: he starts with the base and then adds to it new elements until the house is ready. There exists, anyhow, an approach of an artist creating a sculpture: he takes something large and then deletes extra parts of it. Is there something like “artist’s way” to represent linear subspaces and affine subspaces? The answer is positive and very instructive.

Affine subspaces and systems of linear equations

Let L be a linear subspace. According to Theorem A.2.2.(i), it is an orthogonal complement – namely, the orthogonal complement to the linear subspace L^\perp . Now let a_1, \dots, a_m be a finite spanning set in L^\perp . A vector x which is orthogonal to a_1, \dots, a_m is orthogonal to the entire L^\perp (since every vector from L^\perp is a linear combination of a_1, \dots, a_m and the inner product is bilinear); and of course vice versa, a vector orthogonal to the entire L^\perp is orthogonal to a_1, \dots, a_m . We see that

$$L = (L^\perp)^\perp = \{x \mid a_i^T x = 0, i = 1, \dots, m\}. \quad (\text{A.3.4})$$

Thus, we get a very important, although simple,

Proposition A.3.6 [“Outer” description of a linear subspace] *Every linear subspace L in \mathbf{R}^n is a set of solutions to a homogeneous linear system of equations*

$$a_i^T x = 0, i = 1, \dots, m, \quad (\text{A.3.5})$$

given by properly chosen m and vectors a_1, \dots, a_m .

Proposition A.3.6 is an “if and only if” statement: as we remember from Example A.1.3.A.4, solution set to a homogeneous system of linear equations with n variables always is a linear subspace in \mathbf{R}^n .

From Proposition A.3.6 and the facts we know about the dimension we can easily derive several important consequences:

- Systems (A.3.5) which define a given linear subspace L are exactly the systems given by the vectors a_1, \dots, a_m which span L^\perp ³⁾
- The smallest possible number m of equations in (A.3.5) is the dimension of L^\perp , i.e., by Remark A.2.2, is $\text{codim } L \equiv n - \dim L$ ⁴⁾

Now, an affine subspace M is, by definition, a translation of a linear subspace: $M = a + L$. As we know, vectors x from L are exactly the solutions of certain *homogeneous* system of linear equations

$$a_i^T x = 0, i = 1, \dots, m.$$

It is absolutely clear that adding to these vectors a fixed vector a , we get exactly the set of solutions to the *inhomogeneous* solvable linear system

$$a_i^T x = b_i \equiv a_i^T a, i = 1, \dots, m.$$

Vice versa, the set of solutions to a *solvable* system of linear equations

$$a_i^T x = b_i, i = 1, \dots, m,$$

with n variables is the sum of a particular solution to the system and the solution set to the corresponding homogeneous system (the latter set, as we already know, is a linear subspace in \mathbf{R}^n), i.e., is an affine subspace. Thus, we get the following

Proposition A.3.7 [“Outer” description of an affine subspace]

Every affine subspace $M = a + L$ in \mathbf{R}^n is a set of solutions to a solvable linear system of equations

$$a_i^T x = b_i, i = 1, \dots, m, \quad (\text{A.3.6})$$

given by properly chosen m and vectors a_1, \dots, a_m .

Vice versa, the set of all solutions to a solvable system of linear equations with n variables is an affine subspace in \mathbf{R}^n .

The linear subspace L associated with M is exactly the set of solutions of the homogeneous (with the right hand side set to 0) version of system (A.3.6).

We see, in particular, that an affine subspace always is closed.

³⁾the reasoning which led us to Proposition A.3.6 says that $[a_1, \dots, a_m \text{ span } L^\perp] \Rightarrow [(A.3.5) \text{ defines } L]$; now we claim that the inverse also is true

⁴⁾to make this statement true also in the extreme case when $L = \mathbf{R}^n$ (i.e., when $\text{codim } L = 0$), we from now on make a convention that an *empty* set of equations or inequalities defines, as the solution set, the entire space

Comment. The “outer” description of a linear subspace/affine subspace – the “artist’s” one – is in many cases much more useful than the “inner” description via linear/affine combinations (the “worker’s” one). E.g., with the outer description it is very easy to check whether a given vector belongs or does not belong to a given linear subspace/affine subspace, which is not that easy with the inner one⁵⁾. In fact both descriptions are “complementary” to each other and perfectly well work in parallel: what is difficult to see with one of them, is clear with another. The idea of using “inner” and “outer” descriptions of the entities we meet with – linear subspaces, affine subspaces, convex sets, optimization problems – the general idea of *duality* – is, I would say, the main driving force of Convex Analysis and Optimization, and in the sequel we would all the time meet with different implementations of this fundamental idea.

A.3.5 Structure of the simplest affine subspaces

This small subsection deals mainly with terminology. According to their dimension, affine subspaces in \mathbf{R}^n are named as follows:

- Subspaces of dimension 0 are translations of the only 0-dimensional linear subspace $\{0\}$, i.e., are singleton sets – vectors from \mathbf{R}^n . These subspaces are called *points*; a point is a solution to a square system of linear equations with nonsingular matrix.
- Subspaces of dimension 1 (lines). These subspaces are translations of one-dimensional linear subspaces of \mathbf{R}^n . A one-dimensional linear subspace has a single-element basis given by a nonzero vector d and is comprised of all multiples of this vector. Consequently, line is a set of the form

$$\{y = a + td \mid t \in \mathbf{R}\}$$

given by a pair of vectors a (the origin of the line) and d (the direction of the line), $d \neq 0$. The origin of the line and its direction are not uniquely defined by the line; you can choose as origin any point on the line and multiply a particular direction by nonzero reals.

In the barycentric coordinates a line is described as follows:

$$l = \{\lambda_0 y_0 + \lambda_1 y_1 \mid \lambda_0 + \lambda_1 = 1\} = \{\lambda y_0 + (1 - \lambda) y_1 \mid \lambda \in \mathbf{R}\},$$

where y_0, y_1 is an affine basis of l ; you can choose as such a basis any pair of distinct points on the line.

The “outer” description a line is as follows: it is the set of solutions to a linear system with n variables and $n - 1$ linearly independent equations.

- Subspaces of dimension > 2 and $< n - 1$ have no special names; sometimes they are called affine planes of such and such dimension.
- Affine subspaces of dimension $n - 1$, due to important role they play in Convex Analysis, have a special name – they are called *hyperplanes*. The outer description of a hyperplane is that a hyperplane is the solution set of a *single* linear equation

$$a^T x = b$$

⁵⁾in principle it is not difficult to certify that a given point belongs to, say, a linear subspace given as the linear span of some set – it suffices to point out a representation of the point as a linear combination of vectors from the set. But how could you certify that the point does *not* belong to the subspace?

with nontrivial left hand side ($a \neq 0$). In other words, a hyperplane is the level set $a(x) = \text{const}$ of a nonconstant linear form $a(x) = a^T x$.

- The “largest possible” affine subspace – the one of dimension n – is unique and is the entire \mathbf{R}^n . This subspace is given by an empty system of linear equations.

Appendix B

Prerequisites from Real Analysis

B.1 Space \mathbf{R}^n : Metric Structure and Topology

Euclidean structure on the space \mathbf{R}^n gives rise to a number of extremely important *metric* notions – distances, convergence, etc. For the sake of definiteness, we associate these notions with the standard inner product $x^T y$.

B.1.1 Euclidean norm and distances

By positive definiteness, the quantity $x^T x$ always is nonnegative, so that the quantity

$$|x| \equiv \|x\|_2 = \sqrt{x^T x} = \sqrt{x_1^2 + x_2^2 + \dots + x_n^2}$$

is well-defined; this quantity is called the (standard) *Euclidean norm* of vector x (or simply the norm of x) and is treated as the distance from the origin to x . The distance between two arbitrary points $x, y \in \mathbf{R}^n$ is, by definition, the norm $|x - y|$ of the difference $x - y$. The notions we have defined satisfy all basic requirements on the general notions of a norm and distance, specifically:

1. Positivity of norm: *The norm of a vector always is nonnegative; it is zero if and only if the vector is zero:*

$$|x| \geq 0 \quad \forall x; \quad |x| = 0 \Leftrightarrow x = 0.$$

2. Homogeneity of norm: *When a vector is multiplied by a real, its norm is multiplied by the absolute value of the real:*

$$|\lambda x| = |\lambda| \cdot |x| \quad \forall (x \in \mathbf{R}^n, \lambda \in \mathbf{R}).$$

3. Triangle inequality: *Norm of the sum of two vectors is \leq the sum of their norms:*

$$|x + y| \leq |x| + |y| \quad \forall (x, y \in \mathbf{R}^n).$$

In contrast to the properties of positivity and homogeneity, which are absolutely evident, the Triangle inequality is not trivial and definitely requires a proof. The proof goes through a fact which is extremely important by its own right – the *Cauchy Inequality*, which perhaps is the most frequently used inequality in Mathematics:

Theorem B.1.1 [Cauchy's Inequality] *The absolute value of the inner product of two vectors does not exceed the product of their norms:*

$$|x^T y| \leq |x||y| \quad \forall (x, y \in \mathbf{R}^n)$$

and is equal to the product of the norms if and only if one of the vectors is proportional to the other one:

$$|x^T y| = |x||y| \Leftrightarrow \{\exists \alpha : x = \alpha y \text{ or } \exists \beta : y = \beta x\}$$

Proof is immediate: we may assume that both x and y are nonzero (otherwise the Cauchy inequality clearly is equality, and one of the vectors is constant times (specifically, zero times) the other one, as announced in Theorem). Assuming $x, y \neq 0$, consider the function

$$f(\lambda) = (x - \lambda y)^T (x - \lambda y) = x^T x - 2\lambda x^T y + \lambda^2 y^T y.$$

By positive definiteness of the inner product, this function – which is a second order polynomial – is nonnegative on the entire axis, whence the discriminant of the polynomial

$$(x^T y)^2 - (x^T x)(y^T y)$$

is nonpositive:

$$(x^T y)^2 \leq (x^T x)(y^T y).$$

Taking square roots of both sides, we arrive at the Cauchy Inequality. We also see that the inequality is equality if and only if the discriminant of the second order polynomial $f(\lambda)$ is zero, i.e., if and only if the polynomial has a (multiple) real root; but due to positive definiteness of inner product, $f(\cdot)$ has a root λ if and only if $x = \lambda y$, which proves the second part of Theorem. ■

From Cauchy's Inequality to the Triangle Inequality: Let $x, y \in \mathbf{R}^n$. Then

$$\begin{aligned} |x + y|^2 &= (x + y)^T (x + y) && \text{[definition of norm]} \\ &= x^T x + y^T y + 2x^T y && \text{[opening parentheses]} \\ &\leq \underbrace{x^T x}_{|x|^2} + \underbrace{y^T y}_{|y|^2} + 2|x||y| && \text{[Cauchy's Inequality]} \\ &= (|x| + |y|)^2 \\ \Rightarrow |x + y| &\leq |x| + |y| && \blacksquare \end{aligned}$$

The properties of norm (i.e., of the distance to the origin) we have established induce properties of the distances between pairs of arbitrary points in \mathbf{R}^n , specifically:

1. Positivity of distances: *The distance $|x - y|$ between two points is positive, except for the case when the points coincide ($x = y$), when the distance between x and y is zero;*
2. Symmetry of distances: *The distance from x to y is the same as the distance from y to x :*

$$|x - y| = |y - x|;$$

3. Triangle inequality for distances: *For every three points x, y, z , the distance from x to z does not exceed the sum of distances between x and y and between y and z :*

$$|z - x| \leq |y - x| + |z - y| \quad \forall (x, y, z \in \mathbf{R}^n)$$

B.1.2 Convergence

Equipped with distances, we can define the fundamental notion of *convergence of a sequence of vectors*. Specifically, we say that a sequence x^1, x^2, \dots of vectors from \mathbf{R}^n converges to a vector \bar{x} , or, equivalently, that \bar{x} is the limit of the sequence $\{x^i\}$ (notation: $\bar{x} = \lim_{i \rightarrow \infty} x^i$), if the distances from \bar{x} to x^i go to 0 as $i \rightarrow \infty$:

$$\bar{x} = \lim_{i \rightarrow \infty} x^i \Leftrightarrow |\bar{x} - x^i| \rightarrow 0, i \rightarrow \infty,$$

or, which is the same, for every $\epsilon > 0$ there exists $i = i(\epsilon)$ such that the distance between every point x^i , $i \geq i(\epsilon)$, and \bar{x} does not exceed ϵ :

$$\{|\bar{x} - x^i| \rightarrow 0, i \rightarrow \infty\} \Leftrightarrow \{\forall \epsilon > 0 \exists i(\epsilon) : i \geq i(\epsilon) \Rightarrow |\bar{x} - x^i| \leq \epsilon\}.$$

Exercise B.1 Verify the following facts:

1. $\bar{x} = \lim_{i \rightarrow \infty} x^i$ if and only if for every $j = 1, \dots, n$ the coordinates $\# j$ of the vectors x^i converge, as $i \rightarrow \infty$, to the coordinate $\# j$ of the vector \bar{x} ;
2. If a sequence converges, its limit is uniquely defined;
3. Convergence is compatible with linear operations:
 - if $x^i \rightarrow x$ and $y^i \rightarrow y$ as $i \rightarrow \infty$, then $x^i + y^i \rightarrow x + y$ as $i \rightarrow \infty$;
 - if $x^i \rightarrow x$ and $\lambda_i \rightarrow \lambda$ as $i \rightarrow \infty$, then $\lambda_i x^i \rightarrow \lambda x$ as $i \rightarrow \infty$.

B.1.3 Closed and open sets

After we have in our disposal distance and convergence, we can speak about *closed* and *open* sets:

- A set $X \subset \mathbf{R}^n$ is called *closed*, if it contains limits of all converging sequences of elements of X :

$$\left\{ x^i \in X, x = \lim_{i \rightarrow \infty} x^i \right\} \Rightarrow x \in X$$

- A set $X \subset \mathbf{R}^n$ is called *open*, if whenever x belongs to X , all points close enough to x also belong to X :

$$\forall (x \in X) \exists (\delta > 0) : |x' - x| < \delta \Rightarrow x' \in X.$$

An open set containing a point x is called a *neighbourhood* of x .

Examples of closed sets: (1) \mathbf{R}^n ; (2) \emptyset ; (3) the sequence $x^i = (i, 0, \dots, 0)$, $i = 1, 2, 3, \dots$;

(4) $\{x \in \mathbf{R}^n : \sum_{i=1}^n a_{ij}x_j = 0, i = 1, \dots, m\}$ (in other words: a linear subspace in \mathbf{R}^n

always is closed, see Proposition A.3.6); (5) $\{x \in \mathbf{R}^n : \sum_{i=1}^n a_{ij}x_j = b_i, i = 1, \dots, m\}$

(in other words: an affine subset of \mathbf{R}^n always is closed, see Proposition A.3.7); (6)

Any finite subset of \mathbf{R}^n

Examples of non-closed sets: (1) $\mathbf{R}^n \setminus \{0\}$; (2) the sequence $x^i = (1/i, 0, \dots, 0)$, $i = 1, 2, 3, \dots$; (3) $\{x \in \mathbf{R}^n : x_j > 0, j = 1, \dots, n\}$; (4) $\{x \in \mathbf{R}^n : \sum_{i=1}^n x_i > 5\}$.

Examples of open sets: (1) \mathbf{R}^n ; (2) \emptyset ; (3) $\{x \in \mathbf{R}^n : \sum_{j=1}^n a_{ij}x_j > b_i, i = 1, \dots, m\}$; (4) complement of a finite set.

Examples of non-open sets: (1) A nonempty finite set; (2) the sequence $x^i = (1/i, 0, \dots, 0)$, $i = 1, 2, 3, \dots$, and the sequence $x^i = (i, 0, 0, \dots, 0)$, $i = 1, 2, 3, \dots$; (3) $\{x \in \mathbf{R}^n : x_j \geq 0, j = 1, \dots, n\}$; (4) $\{x \in \mathbf{R}^n : \sum_{i=1}^n x_i \geq 5\}$.

Exercise B.2 Mark in the list to follows those sets which are closed and those which are open:

1. All vectors with integer coordinates
2. All vectors with rational coordinates
3. All vectors with positive coordinates
4. All vectors with nonnegative coordinates
5. $\{x : |x| < 1\}$;
6. $\{x : |x| = 1\}$;
7. $\{x : |x| \leq 1\}$;
8. $\{x : |x| \geq 1\}$;
9. $\{x : |x| > 1\}$;
10. $\{x : 1 < |x| \leq 2\}$.

Verify the following facts

1. A set $X \subset \mathbf{R}^n$ is closed if and only if its complement $\bar{X} = \mathbf{R}^n \setminus X$ is open;
2. Intersection of every family (finite or infinite) of closed sets is closed. Union of every family (finite or infinite) of open sets is open.
3. Union of finitely many closed sets is closed. Intersection of finitely many open sets is open.

B.1.4 Local compactness of \mathbf{R}^n

A fundamental fact about convergence in \mathbf{R}^n , which in certain sense is characteristic for this series of spaces, is the following

Theorem B.1.2 From every bounded sequence $\{x^i\}_{i=1}^\infty$ of points from \mathbf{R}^n one can extract a converging subsequence $\{x^{i_j}\}_{j=1}^\infty$. Equivalently: A closed and bounded subset X of \mathbf{R}^n is compact, i.e., a set possessing the following two equivalent to each other properties:

- (i) From every sequence of elements of X one can extract a subsequence which converges to certain point of X ;

(ii) From every open covering of X (i.e., a family $\{U_\alpha\}_{\alpha \in A}$ of open sets such that $X \subset \bigcup_{\alpha \in A} U_\alpha$) one can extract a finite sub-covering, i.e., a finite subset of indices $\alpha_1, \dots, \alpha_N$ such that $X \subset \bigcup_{i=1}^N U_{\alpha_i}$.

B.2 Continuous functions on \mathbf{R}^n

B.2.1 Continuity of a function

Let $X \subset \mathbf{R}^n$ and $f(x) : X \rightarrow \mathbf{R}^m$ be a function (another name – mapping) defined on X and taking values in \mathbf{R}^m .

1. f is called *continuous at a point* $\bar{x} \in X$, if for every sequence x^i of points of X converging to \bar{x} the sequence $f(x^i)$ converges to $f(\bar{x})$. Equivalent definition:

$f : X \rightarrow \mathbf{R}^m$ is continuous at $\bar{x} \in X$, if for every $\epsilon > 0$ there exists $\delta > 0$ such that

$$x \in X, |x - \bar{x}| < \delta \Rightarrow |f(x) - f(\bar{x})| < \epsilon.$$

2. f is called *continuous on X* , if f is continuous at every point from X . Equivalent definition: f preserves convergence: whenever a sequence of points $x^i \in X$ converges to a point $x \in X$, the sequence $f(x^i)$ converges to $f(x)$.

Examples of continuous mappings:

1. An *affine* mapping

$$f(x) = \begin{bmatrix} \sum_{j=1}^m A_{1j}x_j + b_1 \\ \vdots \\ \sum_{j=1}^m A_{mj}x_j + b_m \end{bmatrix} \equiv Ax + b : \mathbf{R}^n \rightarrow \mathbf{R}^m$$

is continuous on the entire \mathbf{R}^n (and thus – on every subset of \mathbf{R}^n) (check it!).

2. The norm $|x|$ is a continuous on \mathbf{R}^n (and thus – on every subset of \mathbf{R}^n) real-valued function (check it!).

Exercise B.3 • Consider the function

$$f(x_1, x_2) = \begin{cases} \frac{x_1^2 - x_2^2}{x_1^2 + x_2^2}, & (x_1, x_2) \neq 0 \\ 0, & x_1 = x_2 = 0 \end{cases} : \mathbf{R}^2 \rightarrow \mathbf{R}.$$

Check whether this function is continuous on the following sets:

1. \mathbf{R}^2 ;
2. $\mathbf{R}^2 \setminus \{0\}$;
3. $\{x \in \mathbf{R}^2 : x_1 = 0\}$;

4. $\{x \in \mathbf{R}^2 : x_2 = 0\};$
 5. $\{x \in \mathbf{R}^2 : x_1 + x_2 = 0\};$
 6. $\{x \in \mathbf{R}^2 : x_1 - x_2 = 0\};$
 7. $\{x \in \mathbf{R}^2 : |x_1 - x_2| \leq x_1^4 + x_2^4\};$
- Let $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be a continuous mapping. Mark those of the following statements which always are true:
 1. If U is an open set in \mathbf{R}^m , then so is the set $f^{-1}(U) = \{x : f(x) \in U\};$
 2. If U is an open set in \mathbf{R}^n , then so is the set $f(U) = \{f(x) : x \in U\};$
 3. If F is a closed set in \mathbf{R}^m , then so is the set $f^{-1}(F) = \{x : f(x) \in F\};$
 4. If F is an closed set in \mathbf{R}^n , then so is the set $f(F) = \{f(x) : x \in F\}.$

B.2.2 Elementary continuity-preserving operations

All “elementary” operations with mappings preserve continuity. Specifically,

Theorem B.2.1 *Let X be a subset in \mathbf{R}^n .*

(i) [stability of continuity w.r.t. linear operations] *If $f_1(x), f_2(x)$ are continuous functions on X taking values in \mathbf{R}^m and $\lambda_1(x), \lambda_2(x)$ are continuous real-valued functions on X , then the function*

$$f(x) = \lambda_1(x)f_1(x) + \lambda_2(x)f_2(x) : X \rightarrow \mathbf{R}^m$$

is continuous on X ;

(ii) [stability of continuity w.r.t. superposition] *Let*

- $X \subset \mathbf{R}^n, Y \subset \mathbf{R}^m;$
- $f : X \rightarrow \mathbf{R}^m$ be a continuous mapping such that $f(x) \in Y$ for every $x \in X$;
- $g : Y \rightarrow \mathbf{R}^k$ be a continuous mapping.

Then the composite mapping

$$h(x) = g(f(x)) : X \rightarrow \mathbf{R}^k$$

is continuous on X .

B.2.3 Basic properties of continuous functions on \mathbf{R}^n

The basic properties of continuous functions on \mathbf{R}^n can be summarized as follows:

Theorem B.2.2 *Let X be a nonempty closed and bounded subset of \mathbf{R}^n .*

(i) *If a mapping $f : X \rightarrow \mathbf{R}^m$ is continuous on X , it is bounded on X : there exists $C < \infty$ such that $|f(x)| \leq C$ for all $x \in X$.*

Proof. Assume, on the contrary to what should be proved, that f is unbounded, so that for every i there exists a point $x^i \in X$ such that $|f(x^i)| > i$. By Theorem B.1.2, we can extract from the sequence $\{x^i\}$ a subsequence $\{x^{i_j}\}_{j=1}^{\infty}$ which converges to a point $\bar{x} \in X$. The real-valued function $g(x) = |f(x)|$ is continuous (as the superposition of two continuous mappings, see Theorem B.2.1.(ii)) and therefore its values at the points x^{i_j} should converge, as $j \rightarrow \infty$, to its value at \bar{x} ; on the other hand, $g(x^{i_j}) \geq i_j \rightarrow \infty$ as $j \rightarrow \infty$, and we get the desired contradiction.

(ii) If a mapping $f : X \rightarrow \mathbf{R}^m$ is continuous on X , it is uniformly continuous: for every $\epsilon > 0$ there exists $\delta > 0$ such that

$$x, y \in X, |x - y| < \delta \Rightarrow |f(x) - f(y)| < \epsilon.$$

Proof. Assume, on the contrary to what should be proved, that there exists $\epsilon > 0$ such that for every $\delta > 0$ one can find a pair of points x, y in X such that $|x - y| < \delta$ and $|f(x) - f(y)| \geq \epsilon$. In particular, for every $i = 1, 2, \dots$ we can find two points x^i, y^i in X such that $|x^i - y^i| \leq 1/i$ and $|f(x^i) - f(y^i)| \geq \epsilon$. By Theorem B.1.2, we can extract from the sequence $\{x^i\}$ a subsequence $\{x^{i_j}\}_{j=1}^\infty$ which converges to certain point $\bar{x} \in X$. Since $|y^{i_j} - x^{i_j}| \leq 1/i_j \rightarrow 0$ as $j \rightarrow \infty$, the sequence $\{y^{i_j}\}_{j=1}^\infty$ converges to the same point \bar{x} as the sequence $\{x^{i_j}\}_{j=1}^\infty$ (why?) Since f is continuous, we have

$$\lim_{j \rightarrow \infty} f(y^{i_j}) = f(\bar{x}) = \lim_{j \rightarrow \infty} f(x^{i_j}),$$

whence $\lim_{j \rightarrow \infty} (f(x^{i_j}) - f(y^{i_j})) = 0$, which contradicts the fact that $|f(x^{i_j}) - f(y^{i_j})| \geq \epsilon > 0$ for all j .

(iii) Let f be a real-valued continuous function on X . The f attains its minimum on X :

$$\operatorname{Argmin}_X f \equiv \{x \in X : f(x) = \inf_{y \in X} f(y)\} \neq \emptyset,$$

same as f attains its maximum at certain points of X :

$$\operatorname{Argmax}_X f \equiv \{x \in X : f(x) = \sup_{y \in X} f(y)\} \neq \emptyset.$$

Proof: Let us prove that f attains its maximum on X (the proof for minimum is completely similar). Since f is bounded on X by (i), the quantity

$$f^* = \sup_{x \in X} f(x)$$

is finite; of course, we can find a sequence $\{x^i\}$ of points from X such that $f^* = \lim_{i \rightarrow \infty} f(x^i)$. By Theorem B.1.2, we can extract from the sequence $\{x^i\}$ a subsequence $\{x^{i_j}\}_{j=1}^\infty$ which converges to certain point $\bar{x} \in X$. Since f is continuous on X , we have

$$f(\bar{x}) = \lim_{j \rightarrow \infty} f(x^{i_j}) = \lim_{i \rightarrow \infty} f(x^i) = f^*,$$

so that the maximum of f on X indeed is achieved (e.g., at the point \bar{x}).

Exercise B.4 Prove that in general no one of the three statements in Theorem B.2.2 remains valid when X is closed, but not bounded, same as when X is bounded, but not closed.

B.3 Differentiable functions on \mathbf{R}^n

B.3.1 The derivative

The reader definitely is familiar with the notion of derivative of a real-valued function $f(x)$ of real variable x :

$$f'(x) = \lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

This definition does not work when we pass from functions of single real variable to functions of several real variables, or, which is the same, to functions with vector arguments. Indeed, in this case the shift in the argument Δx should be a vector, and we do not know what does it mean to divide by a vector...

A proper way to extend the notion of the derivative to real- and vector-valued functions of vector argument is to realize what in fact is the meaning of the derivative in the univariate case. What $f'(x)$ says to us is *how to approximate f in a neighbourhood of x by a linear function*. Specifically, *if $f'(x)$ exists, then the linear function $f'(x)\Delta x$ of Δx approximates the change $f(x + \Delta x) - f(x)$ in f up to a remainder which is of highest order as compared with Δx as $\Delta x \rightarrow 0$:*

$$|f(x + \Delta x) - f(x) - f'(x)\Delta x| \leq \bar{o}(|\Delta x|) \text{ as } \Delta x \rightarrow 0.$$

In the above formula, we meet with the notation $\bar{o}(|\Delta x|)$, and here is the explanation of this notation:

$\bar{o}(|\Delta x|)$ is a common name of all functions $\phi(\Delta x)$ of Δx which are well-defined in a neighbourhood of the point $\Delta x = 0$ on the axis, vanish at the point $\Delta x = 0$ and are such that

$$\frac{\phi(\Delta x)}{|\Delta x|} \rightarrow 0 \text{ as } \Delta x \rightarrow 0.$$

For example,

1. $(\Delta x)^2 = \bar{o}(|\Delta x|)$, $\Delta x \rightarrow 0$,
2. $|\Delta x|^{1.01} = \bar{o}(|\Delta x|)$, $\Delta x \rightarrow 0$,
3. $\sin^2(\Delta x) = \bar{o}(|\Delta x|)$, $\Delta x \rightarrow 0$,
4. $\Delta x \neq \bar{o}(|\Delta x|)$, $\Delta x \rightarrow 0$.

Later on we shall meet with the notation “ $\bar{o}(|\Delta x|^k)$ as $\Delta x \rightarrow 0$ ”, where k is a positive integer. The definition is completely similar to the one for the case of $k = 1$:

$\bar{o}(|\Delta x|^k)$ is a common name of all functions $\phi(\Delta x)$ of Δx which are well-defined in a neighbourhood of the point $\Delta x = 0$ on the axis, vanish at the point $\Delta x = 0$ and are such that

$$\frac{\phi(\Delta x)}{|\Delta x|^k} \rightarrow 0 \text{ as } \Delta x \rightarrow 0.$$

Note that if $f(\cdot)$ is a function defined in a neighbourhood of a point x on the axis, then there perhaps are many linear functions $a\Delta x$ of Δx which well approximate $f(x + \Delta x) - f(x)$, in the sense that the remainder in the approximation

$$f(x + \Delta x) - f(x) - a\Delta x$$

tends to 0 as $\Delta x \rightarrow 0$; among these approximations, however, there exists *at most one* which approximates $f(x + \Delta x) - f(x)$ “very well” – so that the remainder is $\bar{o}(|\Delta x|)$, and not merely tends to 0 as $\Delta x \rightarrow 0$. Indeed, if

$$f(x + \Delta x) - f(x) - a\Delta x = \bar{o}(|\Delta x|),$$

then, dividing both sides by Δx , we get

$$\frac{f(x + \Delta x) - f(x)}{\Delta x} - a = \frac{\bar{o}(|\Delta x|)}{\Delta x};$$

by definition of $\bar{o}(\cdot)$, the right hand side in this equality tends to 0 as $\Delta x \rightarrow 0$, whence

$$a = \lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x) - f(x)}{\Delta x} = f'(x).$$

Thus, if a linear function $a\Delta x$ of Δx approximates the change $f(x + \Delta x) - f(x)$ in f up to the remainder which is $\bar{o}(|\Delta x|)$ as $\Delta x \rightarrow 0$, then a is the derivative of f at x . You can easily verify that the inverse statement also is true: if the derivative of f at x exists, then the linear function $f'(x)\Delta x$ of Δx approximates the change $f(x + \Delta x) - f(x)$ in f up to the remainder which is $\bar{o}(|\Delta x|)$ as $\Delta x \rightarrow 0$.

The advantage of the “ $\bar{o}(|\Delta x|)$ ”-definition of derivative is that it can be naturally extended onto vector-valued functions of vector arguments (you should just replace “axis” with \mathbf{R}^n in the definition of \bar{o}) and enlightens the essence of the notion of derivative: when it exists, this is exactly the linear function of Δx which approximates the change $f(x + \Delta x) - f(x)$ in f up to a remainder which is $\bar{o}(|\Delta x|)$. The precise definition is as follows:

Definition B.3.1 [Frechet differentiability] *Let f be a function which is well-defined in a neighbourhood of a point $x \in \mathbf{R}^n$ and takes values in \mathbf{R}^m . We say that f is differentiable at x , if there exists a linear function $Df(x)[\Delta x]$ of $\Delta x \in \mathbf{R}^n$ taking values in \mathbf{R}^m which approximates the change $f(x + \Delta x) - f(x)$ in f up to a remainder which is $\bar{o}(|\Delta x|)$:*

$$|f(x + \Delta x) - f(x) - Df(x)[\Delta x]| \leq \bar{o}(|\Delta x|). \quad (\text{B.3.1})$$

Equivalently: a function f which is well-defined in a neighbourhood of a point $x \in \mathbf{R}^n$ and takes values in \mathbf{R}^m is called differentiable at x , if there exists a linear function $Df(x)[\Delta x]$ of $\Delta x \in \mathbf{R}^n$ taking values in \mathbf{R}^m such that for every $\epsilon > 0$ there exists $\delta > 0$ satisfying the relation

$$|\Delta x| \leq \delta \Rightarrow |f(x + \Delta x) - f(x) - Df(x)[\Delta x]| \leq \epsilon |\Delta x|.$$

B.3.2 Derivative and directional derivatives

We have defined what does it mean that a function $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ is differentiable at a point x , but did not say yet what is the derivative. The reader could guess that the derivative is exactly the “linear function $Df(x)[\Delta x]$ of $\Delta x \in \mathbf{R}^n$ taking values in \mathbf{R}^m which approximates the change $f(x + \Delta x) - f(x)$ in f up to a remainder which is $\leq \bar{o}(|\Delta x|)$ ” participating in the definition of differentiability. The guess is correct, but we cannot merely call the entity participating in the definition the derivative – why do we know that this entity is unique? Perhaps there are many different linear functions of Δx approximating the change in f up to a remainder which is $\bar{o}(|\Delta x|)$. In fact there is no more than a single linear function with this property due to the following observation:

Let f be differentiable at x , and $Df(x)[\Delta x]$ be a linear function participating in the definition of differentiability. Then

$$\forall \Delta x \in \mathbf{R}^n : \quad Df(x)[\Delta x] = \lim_{t \rightarrow +0} \frac{f(x + t\Delta x) - f(x)}{t}. \quad (\text{B.3.2})$$

In particular, the derivative $Df(x)[\cdot]$ is uniquely defined by f and x .

Proof. We have

$$\begin{aligned}
 |f(x + t\Delta x) - f(x) - Df(x)[t\Delta x]| &\leq \bar{o}(|t\Delta x|) \\
 &\Downarrow \\
 \left| \frac{f(x + t\Delta x) - f(x)}{t} - \frac{Df(x)[t\Delta x]}{t} \right| &\leq \frac{\bar{o}(|t\Delta x|)}{t} \\
 &\Updownarrow \\
 \left| \frac{f(x + t\Delta x) - f(x)}{t} - Df(x)[\Delta x] \right| &\leq \frac{\bar{o}(|t\Delta x|)}{t} \\
 &\Downarrow \\
 Df(x)[\Delta x] &= \lim_{t \rightarrow +0} \frac{f(x + t\Delta x) - f(x)}{t} \quad \left[\begin{array}{l} \text{passing to limit as } t \rightarrow +0; \\ \text{note that } \frac{\bar{o}(|t\Delta x|)}{t} \rightarrow 0, t \rightarrow +0 \end{array} \right]
 \end{aligned}$$

[since $Df(x)[\cdot]$ is linear]

Pay attention to important remarks as follows:

1. The right hand side limit in (B.3.2) is an important entity called the *directional derivative of f taken at x along (a direction) Δx* ; note that this quantity is defined in the “purely univariate” fashion – by dividing the change in f by the magnitude of a shift in a direction Δx and passing to limit as the magnitude of the shift approaches 0. Relation (B.3.2) says that the derivative, if exists, is, at every Δx , nothing that the directional derivative of f taken at x along Δx . Note, however, that differentiability is much more than the existence of directional derivatives along all directions Δx ; differentiability requires also *the directional derivatives to be “well-organized” – to depend linearly on the direction Δx* . It is easily seen that just existence of directional derivatives does not imply their “good organization”: for example, the Euclidean norm

$$f(x) = |x|$$

at $x = 0$ possesses directional derivatives along all directions:

$$\lim_{t \rightarrow +0} \frac{f(0 + t\Delta x) - f(0)}{t} = |\Delta x|;$$

these derivatives, however, depend *non-linearly* on Δx , so that the Euclidean norm is *not* differentiable at the origin (although is differentiable everywhere outside the origin, but this is another story).

2. It should be stressed that the derivative, if exists, is what it is: *a linear function of $\Delta x \in \mathbf{R}^n$ taking values in \mathbf{R}^m* . As we shall see in a while, we can *represent* this function by something “tractable”, like a vector or a matrix, and can understand how to compute such a representation; however, an intelligent reader should bear in mind that a representation is not exactly the same as *the* represented entity. Sometimes the difference between derivatives and the entities which represent them is reflected in the terminology: what we call the *derivative*, is also called the *differential*, while the word “derivative” is reserved for the vector/matrix representing the differential.

B.3.3 Representations of the derivative

By definition, the derivative of a mapping $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ at a point x is a linear function $Df(x)[\Delta x]$ taking values in \mathbf{R}^m . How could we represent such a function?

Case of $m = 1$ – the gradient. Let us start with real-valued functions (i.e., with the case of $m = 1$); in this case the derivative is a linear real-valued function on \mathbf{R}^n . As we remember, the standard Euclidean structure on \mathbf{R}^n allows to represent every linear function on \mathbf{R}^n as the inner product of the argument with certain fixed vector. In particular, the derivative $Df(x)[\Delta x]$ of a scalar function can be represented as

$$Df(x)[\Delta x] = [\text{vector}]^T \Delta x;$$

what is denoted "vector" in this relation, is called the *gradient* of f at x and is denoted by $\nabla f(x)$:

$$Df(x)[\Delta x] = (\nabla f(x))^T \Delta x. \quad (\text{B.3.3})$$

How to compute the gradient? The answer is given by (B.3.2). Indeed, let us look what (B.3.3) and (B.3.2) say when Δx is the i -th standard basic orth. According to (B.3.3), $Df(x)[e_i]$ is the i -th coordinate of the vector $\nabla f(x)$; according to (B.3.2),

$$Df(x)[e_i] = -Df(x)[-e_i] = -\lim_{t \rightarrow +0} \frac{f(x-te_i)-f(x)}{t} = \lim_{t \rightarrow -0} \frac{f(x+te_i)-f(x)}{t} \left. \vphantom{\lim_{t \rightarrow -0} \frac{f(x+te_i)-f(x)}{t}} \right\} \Rightarrow Df(x)[e_i] = \frac{\partial f(x)}{\partial x_i}.$$

Thus,

If a real-valued function f is differentiable at x , then the first order partial derivatives of f at x exist, and the gradient of f at x is just the vector with the coordinates which are the first order partial derivatives of f taken at x :

$$\nabla f(x) = \begin{bmatrix} \frac{\partial f(x)}{\partial x_1} \\ \vdots \\ \frac{\partial f(x)}{\partial x_n} \end{bmatrix}.$$

The derivative of f , taken at x , is the linear function of Δx given by

$$Df(x)[\Delta x] = (\nabla f(x))^T \Delta x = \sum_{i=1}^n \frac{\partial f(x)}{\partial x_i} (\Delta x)_i.$$

General case – the Jacobian. Now let $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ with $m \geq 1$. In this case, $Df(x)[\Delta x]$, regarded as a function of Δx , is a linear mapping from \mathbf{R}^n to \mathbf{R}^m ; as we remember, the standard way to represent a linear mapping from \mathbf{R}^n to \mathbf{R}^m is to represent it as the multiplication by $m \times n$ matrix:

$$Df(x)[\Delta x] = [m \times n \text{ matrix}] \cdot \Delta x. \quad (\text{B.3.4})$$

What is denoted by "matrix" in (B.3.4), is called the *Jacobian* of f at x and is denoted by $f'(x)$. How to compute the entries of the Jacobian? Here again the answer is readily given by (B.3.2). Indeed, on one hand, we have

$$Df(x)[\Delta x] = f'(x)\Delta x, \quad (\text{B.3.5})$$

whence

$$[Df(x)[e_j]]_i = (f'(x))_{ij}, \quad i = 1, \dots, m, j = 1, \dots, n.$$

On the other hand, denoting

$$f(x) = \begin{bmatrix} f_1(x) \\ \vdots \\ f_m(x) \end{bmatrix},$$

the same computation as in the case of gradient demonstrates that

$$[Df(x)[e_j]]_i = \frac{\partial f_i(x)}{\partial x_j}$$

and we arrive at the following conclusion:

If a vector-valued function $f(x) = (f_1(x), \dots, f_m(x))$ is differentiable at x , then the first order partial derivatives of all f_i at x exist, and the Jacobian of f at x is just the $m \times n$ matrix with the entries $[\frac{\partial f_i(x)}{\partial x_j}]_{i,j}$ (so that the rows in the Jacobian are $[\nabla f_1(x)]^T, \dots, [\nabla f_m(x)]^T$. The derivative of f , taken at x , is the linear vector-valued function of Δx given by

$$Df(x)[\Delta x] = f'(x)\Delta x = \begin{bmatrix} [\nabla f_1(x)]^T \Delta x \\ \vdots \\ [\nabla f_m(x)]^T \Delta x \end{bmatrix}.$$

Remark B.3.1 Note that for a real-valued function f we have defined both the gradient $\nabla f(x)$ and the Jacobian $f'(x)$. These two entities are “nearly the same”, but not exactly the same: the Jacobian is a vector-row, and the gradient is a vector-column linked by the relation

$$f'(x) = (\nabla f(x))^T.$$

Of course, both these representations of the derivative of f yield the same linear approximation of the change in f :

$$Df(x)[\Delta x] = (\nabla f(x))^T \Delta x = f'(x)\Delta x.$$

B.3.4 Existence of the derivative

We have seen that the existence of the derivative of f at a point implies the existence of the first order partial derivatives of the (components f_1, \dots, f_m of) f . The inverse statement is not exactly true – the existence of all first order partial derivatives $\frac{\partial f_i(x)}{\partial x_j}$ not necessarily implies the existence of the derivative; we need a bit more:

Theorem B.3.1 [Sufficient condition for differentiability] *Assume that*

1. *The mapping $f = (f_1, \dots, f_m) : \mathbf{R}^n \rightarrow \mathbf{R}^m$ is well-defined in a neighbourhood U of a point $x_0 \in \mathbf{R}^n$,*
2. *The first order partial derivatives of the components f_i of f exist everywhere in U ,*
and
3. *The first order partial derivatives of the components f_i of f are continuous at the point x_0 .*

Then f is differentiable at the point x_0 .

B.3.5 Calculus of derivatives

The calculus of derivatives is given by the following result:

Theorem B.3.2 (i) [Differentiability and linear operations] *Let $f_1(x)$, $f_2(x)$ be mappings defined in a neighbourhood of $x_0 \in \mathbf{R}^n$ and taking values in \mathbf{R}^m , and $\lambda_1(x)$, $\lambda_2(x)$ be real-valued functions defined in a neighbourhood of x_0 . Assume that $f_1, f_2, \lambda_1, \lambda_2$ are differentiable at x_0 . Then so is the function $f(x) = \lambda_1(x)f_1(x) + \lambda_2(x)f_2(x)$, with the derivative at x_0 given by*

$$\begin{aligned} Df(x_0)[\Delta x] &= [D\lambda_1(x_0)[\Delta x]]f_1(x_0) + \lambda_1(x_0)Df_1(x_0)[\Delta x] \\ &\quad + [D\lambda_2(x_0)[\Delta x]]f_2(x_0) + \lambda_2(x_0)Df_2(x_0)[\Delta x] \\ &\quad \Downarrow \\ f'(x_0) &= f_1(x_0)[\nabla\lambda_1(x_0)]^T + \lambda_1(x_0)f'_1(x_0) \\ &\quad + f_2(x_0)[\nabla\lambda_2(x_0)]^T + \lambda_2(x_0)f'_2(x_0). \end{aligned}$$

(ii) [chain rule] *Let a mapping $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be differentiable at x_0 , and a mapping $g : \mathbf{R}^m \rightarrow \mathbf{R}^n$ be differentiable at $y_0 = f(x_0)$. Then the superposition $h(x) = g(f(x))$ is differentiable at x_0 , with the derivative at x_0 given by*

$$\begin{aligned} Dh(x_0)[\Delta x] &= Dg(y_0)[Df(x_0)[\Delta x]] \\ &\quad \Downarrow \\ h'(x_0) &= g'(y_0)f'(x_0) \end{aligned}$$

If the outer function g is real-valued, then the latter formula implies that

$$\nabla h(x_0) = [f'(x_0)]^T \nabla g(y_0)$$

(recall that for a real-valued function ϕ , $\phi' = (\nabla\phi)^T$).

B.3.6 Computing the derivative

Representations of the derivative via first order partial derivatives normally allow to compute it by the standard Calculus rules, in a completely mechanical fashion, not thinking at all of *what* we are computing. The examples to follow (especially the third of them) demonstrate that it often makes sense to bear in mind *what* is the derivative; this sometimes yield the result much faster than blind implementing Calculus rules.

Example 1: The gradient of an affine function. An *affine* function

$$f(x) = a + \sum_{i=1}^n g_i x_i \equiv a + g^T x : \mathbf{R}^n \rightarrow \mathbf{R}$$

is differentiable at every point (Theorem B.3.1) and its gradient, of course, equals g :

$$\begin{aligned} (\nabla f(x))^T \Delta x &= \lim_{t \rightarrow +0} t^{-1} [f(x + t\Delta x) - f(x)] && \text{[(B.3.2)]} \\ &= \lim_{t \rightarrow +0} t^{-1} [tg^T \Delta x] && \text{[arithmetics]} \end{aligned}$$

and we arrive at

$$\boxed{\nabla(a + g^T x) = g}$$

Example 2: The gradient of a quadratic form. For the time being, let us define a homogeneous quadratic form on \mathbf{R}^n as a function

$$f(x) = \sum_{i,j} A_{ij} x_i x_j = x^T A x,$$

where A is an $n \times n$ matrix. Note that the matrices A and A^T define the same quadratic form, and therefore the symmetric matrix $B = \frac{1}{2}(A + A^T)$ also produces the same quadratic form as A and A^T . It follows that we always may assume (and do assume from now on) that the matrix A producing the quadratic form in question is symmetric.

A quadratic form is a simple polynomial and as such is differentiable at every point (Theorem B.3.1). What is the gradient of f at a point x ? Here is the computation:

$$\begin{aligned} (\nabla f(x))^T \Delta x &= Df(x)[\Delta x] \\ &= \lim_{t \rightarrow +0} [(x + t\Delta x)^T A(x + t\Delta x) - x^T A x] \\ &= \lim_{t \rightarrow +0} [x^T A x + t(\Delta x)^T A x + t x^T A \Delta x + t^2(\Delta x)^T A \Delta x - x^T A x] \quad \text{[(B.3.2)]} \\ &= \lim_{t \rightarrow +0} t^{-1} [2t(Ax)^T \Delta x + t^2(\Delta x)^T A \Delta x] \quad \text{[opening parentheses]} \\ &= 2(Ax)^T \Delta x \quad \text{[arithmetics + symmetry of } A] \end{aligned}$$

We conclude that

$$\boxed{\nabla(x^T A x) = 2Ax}$$

(recall that $A = A^T$).

Example 3: The derivative of the log-det barrier. Let us compute the derivative of the *log-det barrier* (playing an extremely important role in modern optimization)

$$F(X) = \ln \text{Det}(X);$$

here X is an $n \times n$ matrix (or, if you prefer, n^2 -dimensional vector). Note that $F(X)$ is well-defined and differentiable in a neighbourhood of every point \bar{X} with positive determinant (indeed, $\text{Det}(X)$ is a polynomial of the entries of X and thus – is everywhere continuous and differentiable with continuous partial derivatives, while the function $\ln(t)$ is continuous and differentiable on the positive ray; by Theorems B.2.1.(ii), B.3.2.(ii), F is differentiable at every X such that $\text{Det}(X) > 0$). The reader is kindly asked to try to find the derivative of F by the standard techniques; if the result will not be obtained in, say, 30 minutes, please look at the 8-line computation to follow (in this computation, $\text{Det}(\bar{X}) > 0$, and $G(X) = \text{Det}(X)$):

$$\begin{aligned} &DF(\bar{X})[\Delta X] \\ &= D \ln(G(\bar{X}))[DG(\bar{X})[\Delta X]] \quad \text{[chain rule]} \\ &= G^{-1}(\bar{X})DG(\bar{X})[\Delta X] \quad \text{[}\ln'(t) = t^{-1}\text{]} \\ &= \text{Det}^{-1}(\bar{X}) \lim_{t \rightarrow +0} t^{-1} [\text{Det}(\bar{X} + t\Delta X) - \text{Det}(\bar{X})] \quad \text{[definition of } G \text{ and (B.3.2)]} \\ &= \text{Det}^{-1}(\bar{X}) \lim_{t \rightarrow +0} t^{-1} [\text{Det}(\bar{X}(I + t\bar{X}^{-1}\Delta X)) - \text{Det}(\bar{X})] \\ &= \text{Det}^{-1}(\bar{X}) \lim_{t \rightarrow +0} t^{-1} [\text{Det}(\bar{X})(\text{Det}(I + t\bar{X}^{-1}\Delta X) - 1)] \quad \text{[Det}(AB) = \text{Det}(A)\text{Det}(B)] \\ &= \lim_{t \rightarrow +0} t^{-1} [\text{Det}(I + t\bar{X}^{-1}\Delta X) - 1] \\ &= \text{Tr}(\bar{X}^{-1}\Delta X) = \sum_{i,j} [\bar{X}^{-1}]_{ji}(\Delta X)_{ij} \end{aligned}$$

where the concluding equality

$$\lim_{t \rightarrow +0} t^{-1} [\text{Det}(I + tA) - 1] = \text{Tr}(A) \equiv \sum_i A_{ii} \quad (\text{B.3.6})$$

is immediately given by recalling what is the determinant of $I + tA$: this is a polynomial of t which is the sum of products, taken along all diagonals of a $n \times n$ matrix and assigned certain signs, of the entries of $I + tA$. At every one of these diagonals, except for the main one, there are at least two cells with the entries proportional to t , so that the corresponding products do not contribute to the constant and the linear in t terms in $\text{Det}(I + tA)$ and thus do not affect the limit in (B.3.6). The only product which does contribute to the linear and the constant terms in $\text{Det}(I + tA)$ is the product $(1 + tA_{11})(1 + tA_{22}) \dots (1 + tA_{nn})$ coming from the main diagonal; it is clear that in this product the constant term is 1, and the linear in t term is $t(A_{11} + \dots + A_{nn})$, and (B.3.6) follows.

B.3.7 Higher order derivatives

Let $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be a mapping which is well-defined and differentiable at every point x from an open set U . The Jacobian of this mapping $J(x)$ is a mapping from \mathbf{R}^n to the space $\mathbf{R}^{m \times n}$ matrices, i.e., is a mapping taking values in certain \mathbf{R}^M ($M = mn$). The derivative of this mapping, if it exists, is called the *second derivative* of f ; it again is a mapping from \mathbf{R}^n to certain \mathbf{R}^M and as such can be differentiable, and so on, so that we can speak about the second, the third, ... derivatives of a vector-valued function of vector argument. A *sufficient* condition for the existence of k derivatives of f in U is that f is C^k in U , i.e., that all partial derivatives of f of orders $\leq k$ exist and are continuous everywhere in U (cf. Theorem B.3.1).

We have explained what does it mean that f has k derivatives in U ; note, however, that according to the definition, highest order derivatives at a point x are just long vectors; say, the second order derivative of a scalar function f of 2 variables is the Jacobian of the mapping $x \mapsto f'(x) : \mathbf{R}^2 \rightarrow \mathbf{R}^2$, i.e., a mapping from \mathbf{R}^2 to $\mathbf{R}^{2 \times 2} = \mathbf{R}^4$; the third order derivative of f is therefore the Jacobian of a mapping from \mathbf{R}^2 to \mathbf{R}^4 , i.e., a mapping from \mathbf{R}^2 to $\mathbf{R}^{4 \times 2} = \mathbf{R}^8$, and so on. The question which should be addressed now is: *What is a natural and transparent way to represent the highest order derivatives?*

The answer is as follows:

(*) Let $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be C^k on an open set $U \subset \mathbf{R}^n$. The derivative of order $\ell \leq k$ of f , taken at a point $x \in U$, can be naturally identified with a function

$$D^\ell f(x)[\Delta x^1, \Delta x^2, \dots, \Delta x^\ell]$$

of ℓ vector arguments $\Delta x^i \in \mathbf{R}^n$, $i = 1, \dots, \ell$, and taking values in \mathbf{R}^m . This function is linear in every one of the arguments Δx^i , the other arguments being fixed, and is symmetric with respect to permutation of arguments $\Delta x^1, \dots, \Delta x^\ell$.

In terms of f , the quantity $D^\ell f(x)[\Delta x^1, \Delta x^2, \dots, \Delta x^\ell]$ (full name: “the ℓ -th derivative (or differential) of f taken at a point x along the directions $\Delta x^1, \dots, \Delta x^\ell$ ”) is given by

$$D^\ell f(x)[\Delta x^1, \Delta x^2, \dots, \Delta x^\ell] = \frac{\partial^\ell}{\partial t_\ell \partial t_{\ell-1} \dots \partial t_1} \Big|_{t_1 = \dots = t_\ell = 0} f(x + t_1 \Delta x^1 + t_2 \Delta x^2 + \dots + t_\ell \Delta x^\ell). \quad (\text{B.3.7})$$

The explanation to our claims is as follows. Let $f : \mathbf{R} \rightarrow \mathbf{R}^m$ be C^k on an open set $U \subset \mathbf{R}^n$.

1. When $\ell = 1$, (*) says to us that the first order derivative of f , taken at x , is a linear function $Df(x)[\Delta x^1]$ of $\Delta x^1 \in \mathbf{R}^n$, taking values in \mathbf{R}^m , and that the value of this function at every Δx^1 is given by the relation

$$Df(x)[\Delta x^1] = \frac{\partial}{\partial t_1} \Big|_{t_1=0} f(x + t_1 \Delta x^1) \quad (\text{B.3.8})$$

(cf. (B.3.2)), which is in complete accordance with what we already know about the derivative.

2. To understand what is the second derivative, let us take the first derivative $Df(x)[\Delta x^1]$, let us temporarily fix somehow the argument Δx^1 and treat the derivative as a function of x . As a function of x , Δx^1 being fixed, the quantity $Df(x)[\Delta x^1]$ is again a mapping which maps U into \mathbf{R}^m and is differentiable by Theorem B.3.1 (provided, of course, that $k \geq 2$). The derivative of this mapping is certain linear function of $\Delta x \equiv \Delta x^2 \in \mathbf{R}^n$, depending on x as on a parameter; and of course it depends on Δx^1 as on a parameter as well. Thus, the derivative of $Df(x)[\Delta x^1]$ in x is certain function

$$D^2 f(x)[\Delta x^1, \Delta x^2]$$

of $x \in U$ and $\Delta x^1, \Delta x^2 \in \mathbf{R}^n$ and taking values in \mathbf{R}^m . What we know about this function is that it is linear in Δx^2 . In fact, it is also linear in Δx^1 , since it is the derivative in x of certain function (namely, of $Df(x)[\Delta x^1]$) linearly depending on the parameter Δx^1 , so that the derivative of the function in x is linear in the parameter Δx^1 as well (differentiation is a linear operation with respect to a function we are differentiating: summing up functions and multiplying them by real constants, we sum up, respectively, multiply by the same constants, the derivatives). Thus, $D^2 f(x)[\Delta x^1, \Delta x^2]$ is linear in Δx^1 when x and Δx^2 are fixed, and is linear in Δx^2 when x and Δx^1 are fixed. Moreover, we have

$$\begin{aligned} D^2 f(x)[\Delta x^1, \Delta x^2] &= \frac{\partial}{\partial t_2} \Big|_{t_2=0} Df(x + t_2 \Delta x^2)[\Delta x^1] && [\text{cf. (B.3.8)}] \\ &= \frac{\partial}{\partial t_2} \Big|_{t_2=0} \frac{\partial}{\partial t_1} \Big|_{t_1=0} f(x + t_2 \Delta x^2 + t_1 \Delta x^1) && [\text{by (B.3.8)}] \\ &= \frac{\partial^2}{\partial t_2 \partial t_1} \Big|_{t_1=t_2=0} f(x + t_1 \Delta x^1 + t_2 \Delta x^2) \end{aligned} \quad (\text{B.3.9})$$

as claimed in (B.3.7) for $\ell = 2$. The only piece of information about the second derivative which is contained in (*) and is not justified yet is that $D^2 f(x)[\Delta x^1, \Delta x^2]$ is symmetric in $\Delta x^1, \Delta x^2$; but this fact is readily given by the representation (B.3.7), since, as they prove in Calculus, if a function ϕ possesses continuous partial derivatives of orders $\leq \ell$ in a neighbourhood of a point, then these derivatives in this neighbourhood are independent of the order in which they are taken; it follows that

$$\begin{aligned} D^2 f(x)[\Delta x^1, \Delta x^2] &= \frac{\partial^2}{\partial t_2 \partial t_1} \Big|_{t_1=t_2=0} \underbrace{f(x + t_1 \Delta x^1 + t_2 \Delta x^2)}_{\phi(t_1, t_2)} && [(\text{B.3.9})] \\ &= \frac{\partial^2}{\partial t_1 \partial t_2} \Big|_{t_1=t_2=0} \phi(t_1, t_2) \\ &= \frac{\partial^2}{\partial t_1 \partial t_2} \Big|_{t_1=t_2=0} f(x + t_2 \Delta x^2 + t_1 \Delta x^1) \\ &= D^2 f(x)[\Delta x^2, \Delta x^1] && [\text{the same (B.3.9)}] \end{aligned}$$

3. Now it is clear how to proceed: to define $D^3f(x)[\Delta x^1, \Delta x^2, \Delta x^3]$, we fix in the second order derivative $D^2f(x)[\Delta x^1, \Delta x^2]$ the arguments $\Delta x^1, \Delta x^2$ and treat it as a function of x only, thus arriving at a mapping which maps U into \mathbf{R}^m and depends on $\Delta x^1, \Delta x^2$ as on parameters (linearly in every one of them). Differentiating the resulting mapping in x , we arrive at a function $D^3f(x)[\Delta x^1, \Delta x^2, \Delta x^3]$ which by construction is linear in every one of the arguments $\Delta x^1, \Delta x^2, \Delta x^3$ and satisfies (B.3.7); the latter relation, due to the Calculus result on the symmetry of partial derivatives, implies that $D^3f(x)[\Delta x^1, \Delta x^2, \Delta x^3]$ is symmetric in $\Delta x^1, \Delta x^2, \Delta x^3$. After we have in our disposal the third derivative D^3f , we can build from it in the already explained fashion the fourth derivative, and so on, until k -th derivative is defined.

Remark B.3.2 Since $D^\ell f(x)[\Delta x^1, \dots, \Delta x^\ell]$ is linear in every one of Δx^i , we can expand the derivative in a multiple sum:

$$\begin{aligned} \Delta x^i &= \sum_{j=1}^n \Delta x_j^i e_j \\ &\Downarrow \\ D^\ell f(x)[\Delta x^1, \dots, \Delta x^\ell] &= D^\ell f(x) \left[\sum_{j_1=1}^n \Delta x_{j_1}^1 e_{j_1}, \dots, \sum_{j_\ell=1}^n \Delta x_{j_\ell}^\ell e_{j_\ell} \right] \\ &= \sum_{1 \leq j_1, \dots, j_\ell \leq n} D^\ell f(x)[e_{j_1}, \dots, e_{j_\ell}] \Delta x_{j_1}^1 \dots \Delta x_{j_\ell}^\ell \end{aligned} \quad (\text{B.3.10})$$

What is the origin of the coefficients $D^\ell f(x)[e_{j_1}, \dots, e_{j_\ell}]$? According to (B.3.7), one has

$$\begin{aligned} D^\ell f(x)[e_{j_1}, \dots, e_{j_\ell}] &= \left. \frac{\partial^\ell}{\partial t_\ell \partial t_{\ell-1} \dots \partial t_1} \right|_{t_1=\dots=t_\ell=0} f(x + t_1 e_{j_1} + t_2 e_{j_2} + \dots + t_\ell e_{j_\ell}) \\ &= \frac{\partial^\ell}{\partial x_{j_\ell} \partial x_{j_{\ell-1}} \dots \partial x_{j_1}} f(x). \end{aligned}$$

so that the coefficients in (B.3.10) are nothing but the partial derivatives, of order ℓ , of f .

Remark B.3.3 An important particular case of relation (B.3.7) is the one when $\Delta x^1 = \Delta x^2 = \dots = \Delta x^\ell$; let us call the common value of these ℓ vectors d . According to (B.3.7), we have

$$D^\ell f(x)[d, d, \dots, d] = \left. \frac{\partial^\ell}{\partial t_\ell \partial t_{\ell-1} \dots \partial t_1} \right|_{t_1=\dots=t_\ell=0} f(x + t_1 d + t_2 d + \dots + t_\ell d).$$

This relation can be interpreted as follows: consider the function

$$\phi(t) = f(x + td)$$

of a real variable t . Then (check it!)

$$\phi^{(\ell)}(0) = \left. \frac{\partial^\ell}{\partial t_\ell \partial t_{\ell-1} \dots \partial t_1} \right|_{t_1=\dots=t_\ell=0} f(x + t_1 d + t_2 d + \dots + t_\ell d) = D^\ell f(x)[d, \dots, d].$$

In other words, $D^\ell f(x)[d, \dots, d]$ is what is called ℓ -th directional derivative of f taken at x along the direction d ; to define this quantity, we pass from function f of several variables to the univariate function $\phi(t) = f(x + td)$ – restrict f onto the line passing through x and directed by d – and then take the “usual” derivative of order ℓ of the resulting function of single real variable t at the point $t = 0$ (which corresponds to the point x of our line).

Representation of higher order derivatives. k -th order derivative $D^k f(x)[\cdot, \dots, \cdot]$ of a C^k function $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ is what it is – it is a symmetric k -linear mapping on \mathbf{R}^n taking values in \mathbf{R}^m and depending on x as on a parameter. Choosing somehow coordinates in \mathbf{R}^n , we can represent such a mapping in the form

$$D^k f(x)[\Delta x_1, \dots, \Delta x_k] = \sum_{1 \leq i_1, \dots, i_k \leq n} \frac{\partial^k f(x)}{\partial x_{i_k} \partial x_{i_{k-1}} \dots \partial x_{i_1}} (\Delta x_1)_{i_1} \dots (\Delta x_k)_{i_k}.$$

We may say that the derivative can be represented by k -index collection of m -dimensional vectors $\frac{\partial^k f(x)}{\partial x_{i_k} \partial x_{i_{k-1}} \dots \partial x_{i_1}}$. This collection, however, is a difficult-to-handle entity, so that such a representation does not help. There is, however, a case when the collection becomes an entity we know to handle; this is the case of the second-order derivative of a scalar function ($k = 2, m = 1$). In this case, the collection in question is just a symmetric matrix $H(x) = \left[\frac{\partial^2 f(x)}{\partial x_i \partial x_j} \right]_{1 \leq i, j \leq n}$. This matrix (same as the linear map $h \mapsto H(x)h$) is called the *Hessian* of f at x . Note that

$$D^2 f(x)[\Delta x_1, \Delta x_2] = \Delta x_1^T H(x) \Delta x_2.$$

B.3.8 Calculus of C^k mappings

The calculus of C^k mappings can be summarized as follows:

Theorem B.3.3 (i) Let U be an open set in \mathbf{R}^n , $f_1(\cdot), f_2(\cdot) : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be C^k in U , and let real-valued functions $\lambda_1(\cdot), \lambda_2(\cdot)$ be C^k in U . Then the function

$$f(x) = \lambda_1(x)f_1(x) + \lambda_2(x)f_2(x)$$

is C^k in U .

(ii) Let U be an open set in \mathbf{R}^n , V be an open set in \mathbf{R}^m , let a mapping $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be C^k in U and such that $f(x) \in V$ for $x \in U$, and, finally, let a mapping $g : \mathbf{R}^m \rightarrow \mathbf{R}^p$ be C^k in V . Then the superposition

$$h(x) = g(f(x))$$

is C^k in U .

Remark B.3.4 For higher order derivatives, in contrast to the first order ones, there is no simple “chain rule” for computing the derivative of superposition. For example, the second-order derivative of the superposition $h(x) = g(f(x))$ of two C^2 -mappings is given by the formula

$$Dh(x)[\Delta x^1, \Delta x^2] = Dg(f(x))[D^2 f(x)[\Delta x^1, \Delta x^2]] + D^2 g(x)[Df(x)[\Delta x^1], Df(x)[\Delta x^2]]$$

(check it!). We see that both the first- and the second-order derivatives of f and g contribute to the second-order derivative of the superposition h .

The only case when there does exist a simple formula for high order derivatives of a superposition is the case when the inner function is affine: if $f(x) = Ax + b$ and $h(x) = g(f(x)) = g(Ax + b)$ with a C^ℓ mapping g , then

$$D^\ell h(x)[\Delta x^1, \dots, \Delta x^\ell] = D^\ell g(Ax + b)[A\Delta x^1, \dots, A\Delta x^\ell]. \quad (\text{B.3.11})$$

B.3.9 Examples of higher-order derivatives

Example 1: Second-order derivative of an affine function $f(x) = a + b^T x$ is, of course, identically zero. Indeed, as we have seen,

$$Df(x)[\Delta x^1] = b^T \Delta x^1$$

is independent of x , and therefore the derivative of $Df(x)[\Delta x^1]$ in x , which should give us the second derivative $D^2 f(x)[\Delta x^1, \Delta x^2]$, is zero. Clearly, the third, the fourth, etc., derivatives of an affine function are zero as well.

Example 2: Second-order derivative of a homogeneous quadratic form $f(x) = x^T A x$ (A is a symmetric $n \times n$ matrix). As we have seen,

$$Df(x)[\Delta x^1] = 2x^T A \Delta x^1.$$

Differentiating in x , we get

$$D^2 f(x)[\Delta x^1, \Delta x^2] = \lim_{t \rightarrow +0} t^{-1} [2(x + t\Delta x^2)^T A \Delta x^1 - 2x^T A \Delta x^1] = 2(\Delta x^2)^T A \Delta x^1,$$

so that

$$\boxed{D^2 f(x)[\Delta x^1, \Delta x^2] = 2(\Delta x^2)^T A \Delta x^1}$$

Note that the second derivative of a quadratic form is independent of x ; consequently, the third, the fourth, etc., derivatives of a quadratic form are identically zero.

Example 3: Second-order derivative of the log-det barrier $F(X) = \ln \text{Det}(X)$. As we have seen, this function of an $n \times n$ matrix is well-defined and differentiable on the set U of matrices with positive determinant (which is an open set in the space $\mathbf{R}^{n \times n}$ of $n \times n$ matrices). In fact, this function is C^∞ in U . Let us compute its second-order derivative. As we remember,

$$DF(X)[\Delta X^1] = \text{Tr}(X^{-1} \Delta X^1). \quad (\text{B.3.12})$$

To differentiate the right hand side in X , let us first find the derivative of the mapping $G(X) = X^{-1}$ which is defined on the open set of non-degenerate $n \times n$ matrices. We have

$$\begin{aligned} DG(X)[\Delta X] &= \lim_{t \rightarrow +0} t^{-1} [(X + t\Delta X)^{-1} - X^{-1}] \\ &= \lim_{t \rightarrow +0} t^{-1} [(X(I + tX^{-1}\Delta X))^{-1} - X^{-1}] \\ &= \lim_{t \rightarrow +0} t^{-1} [(I + t \underbrace{X^{-1}\Delta X}_Y)^{-1} X^{-1} - X^{-1}] \\ &= \left[\lim_{t \rightarrow +0} t^{-1} [(I + tY)^{-1} - I] \right] X^{-1} \\ &= \left[\lim_{t \rightarrow +0} t^{-1} [I - (I + tY)] (I + tY)^{-1} \right] X^{-1} \\ &= \left[\lim_{t \rightarrow +0} [-Y(I + tY)^{-1}] \right] X^{-1} \\ &= -Y X^{-1} \\ &= -X^{-1} \Delta X X^{-1} \end{aligned}$$

and we arrive at the important by its own right relation

$$\boxed{D(X^{-1})[\Delta X] = -X^{-1}\Delta X X^{-1}, \quad [X \in \mathbf{R}^{n \times n}, \text{Det}(X) \neq 0]}$$

which is the “matrix extension” of the standard relation $(x^{-1})' = -x^{-2}$, $x \in \mathbf{R}$.

Now we are ready to compute the second derivative of the log-det barrier:

$$\begin{aligned} F(X) &= \ln \text{Det}(X) \\ &\Downarrow \\ DF(X)[\Delta X^1] &= \text{Tr}(X^{-1}\Delta X^1) \\ &\Downarrow \\ D^2F(X)[\Delta X^1, \Delta X^2] &= \lim_{t \rightarrow +0} t^{-1} [\text{Tr}((X + t\Delta X^2)^{-1}\Delta X^1) - \text{Tr}(X^{-1}\Delta X^1)] \\ &= \lim_{t \rightarrow +0} \text{Tr}(t^{-1}(X + t\Delta X^2)^{-1}\Delta X^1 - X^{-1}\Delta X^1) \\ &= \lim_{t \rightarrow +0} \text{Tr}([t^{-1}(X + t\Delta X^2)^{-1} - X^{-1}]\Delta X^1) \\ &= \text{Tr}([-X^{-1}\Delta X^2 X^{-1}]\Delta X^1), \end{aligned}$$

and we arrive at the formula

$$\boxed{D^2F(X)[\Delta X^1, \Delta X^2] = -\text{Tr}(X^{-1}\Delta X^2 X^{-1}\Delta X^1) \quad [X \in \mathbf{R}^{n \times n}, \text{Det}(X) > 0]}$$

Since $\text{Tr}(AB) = \text{Tr}(BA)$ (check it!) for all matrices A, B such that the product AB makes sense and is square, the right hand side in the above formula is symmetric in $\Delta X^1, \Delta X^2$, as it should be for the second derivative of a C^2 function.

B.3.10 Taylor expansion

Assume that $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ is C^k in a neighbourhood U of a point \bar{x} . The *Taylor expansion of order k* of f , built at the point \bar{x} , is the function

$$\begin{aligned} F_k(x) &= f(\bar{x}) + \frac{1}{1!} Df(\bar{x})[x - \bar{x}] + \frac{1}{2!} D^2f(\bar{x})[x - \bar{x}, x - \bar{x}] \\ &\quad + \frac{1}{3!} D^3f(\bar{x})[x - \bar{x}, x - \bar{x}, x - \bar{x}] + \dots + \frac{1}{k!} D^k f(\bar{x}) \underbrace{[x - \bar{x}, \dots, x - \bar{x}]}_{k \text{ times}} \end{aligned} \quad (\text{B.3.13})$$

We are already acquainted with the Taylor expansion of order 1

$$F_1(x) = f(\bar{x}) + Df(\bar{x})[x - \bar{x}]$$

– this is the affine function of x which approximates “very well” $f(x)$ in a neighbourhood of \bar{x} , namely, within approximation error $\bar{o}(|x - \bar{x}|)$. Similar fact is true for Taylor expansions of higher order:

Theorem B.3.4 *Let $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be C^k in a neighbourhood of \bar{x} , and let $F_k(x)$ be the Taylor expansion of f at \bar{x} of degree k . Then*

(i) $F_k(x)$ is a vector-valued polynomial of full degree $\leq k$ (i.e., every one of the coordinates of the vector $F_k(x)$ is a polynomial of x_1, \dots, x_n , and the sum of powers of x_i ’s in every term of this polynomial does not exceed k);

(ii) $F_k(x)$ approximates $f(x)$ in a neighbourhood of \bar{x} up to a remainder which is $\bar{o}(|x - \bar{x}|^k)$ as $x \rightarrow \bar{x}$:

For every $\epsilon > 0$, there exists $\delta > 0$ such that

$$|x - \bar{x}| \leq \delta \Rightarrow |F_k(x) - f(x)| \leq \epsilon |x - \bar{x}|^k.$$

$F_k(\cdot)$ is the unique polynomial with components of full degree $\leq k$ which approximates f up to a remainder which is $\bar{o}(|x - \bar{x}|^k)$.

(iii) The value and the derivatives of F_k of orders $1, 2, \dots, k$, taken at \bar{x} , are the same as the value and the corresponding derivatives of f taken at the same point.

As stated in Theorem, $F_k(x)$ approximates $f(x)$ for x close to \bar{x} up to a remainder which is $\bar{o}(|x - \bar{x}|^k)$. In many cases, it is not enough to know that the remainder is “ $\bar{o}(|x - \bar{x}|^k)$ ” — we need an explicit bound on this remainder. The standard bound of this type is as follows:

Theorem B.3.5 *Let k be a positive integer, and let $f : \mathbf{R}^n \rightarrow \mathbf{R}^m$ be C^{k+1} in a ball $B_r = B_r(\bar{x}) = \{x \in \mathbf{R}^n : |x - \bar{x}| < r\}$ of a radius $r > 0$ centered at a point \bar{x} . Assume that the directional derivatives of order $k + 1$, taken at every point of B_r along every unit direction, do not exceed certain $L < \infty$:*

$$|D^{k+1}f(x)[d, \dots, d]| \leq L \quad \forall (x \in B_r) \forall (d, |d| = 1).$$

Then for the Taylor expansion F_k of order k of f taken at \bar{x} one has

$$|f(x) - F_k(x)| \leq \frac{L|x - \bar{x}|^{k+1}}{(k+1)!} \quad \forall (x \in B_r).$$

Thus, in a neighbourhood of \bar{x} the remainder of the k -th order Taylor expansion, taken at \bar{x} , is of order of $L|x - \bar{x}|^{k+1}$, where L is the maximal (over all unit directions and all points from the neighbourhood) magnitude of the directional derivatives of order $k + 1$ of f .

Appendix C

Symmetric matrices

C.1 Spaces of Matrices

Let \mathbf{S}^m be the space of symmetric $m \times m$ matrices, and $\mathbf{M}^{m,n}$ be the space of rectangular $m \times n$ matrices with real entries. From the viewpoint of their linear structure (i.e., the operations of addition and multiplication by reals) \mathbf{S}^m is just the arithmetic linear space $\mathbf{R}^{m(m+1)/2}$ of dimension $\frac{m(m+1)}{2}$: by arranging the elements of a symmetric $m \times m$ matrix X in a single column, say, in the row-by-row order, you get a usual m^2 -dimensional column vector; multiplication of a matrix by a real and addition of matrices correspond to the same operations with the “representing vector(s)”. When X runs through \mathbf{S}^m , the vector representing X runs through $m(m+1)/2$ -dimensional subspace of \mathbf{R}^{m^2} consisting of vectors satisfying the “symmetry condition” – the coordinates coming from symmetric to each other pairs of entries in X are equal to each other. Similarly, $\mathbf{M}^{m,n}$ as a linear space is just \mathbf{R}^{mn} , and it is natural to equip $\mathbf{M}^{m,n}$ with the inner product defined as the usual inner product of the vectors representing the matrices:

$$\langle X, Y \rangle = \sum_{i=1}^m \sum_{j=1}^n X_{ij} Y_{ij} = \text{Tr}(X^T Y).$$

Here Tr stands for the *trace* – the sum of diagonal elements of a (square) matrix. With this inner product (called the *Frobenius inner product*), $\mathbf{M}^{m,n}$ becomes a legitimate Euclidean space, and we may use in connection with this space all notions based upon the Euclidean structure, e.g., the (Frobenius) norm of a matrix

$$\|X\|_2 = \sqrt{\langle X, X \rangle} = \sqrt{\sum_{i=1}^m \sum_{j=1}^n X_{ij}^2} = \sqrt{\text{Tr}(X^T X)}$$

and likewise the notions of orthogonality, orthogonal complement of a linear subspace, etc. The same applies to the space \mathbf{S}^m equipped with the Frobenius inner product; of course, the Frobenius inner product of symmetric matrices can be written without the transposition sign:

$$\langle X, Y \rangle = \text{Tr}(XY), \quad X, Y \in \mathbf{S}^m.$$

C.2 Eigenvalue Decomposition

Let us focus on the space \mathbf{S}^m of symmetric matrices. The most important property of these matrices is as follows:

Theorem C.2.1 [Eigenvalue decomposition] $n \times n$ matrix A is symmetric if and only if it admits an orthonormal system of eigenvectors: there exist orthonormal basis $\{e_1, \dots, e_n\}$ such that

$$Ae_i = \lambda_i e_i, \quad i = 1, \dots, n, \quad (\text{C.2.1})$$

for reals λ_i .

In connection with Theorem C.2.1, it is worthy to recall the following notions and facts:

C.2.A. Eigenvectors and eigenvalues. An eigenvector of an $n \times n$ matrix A is a nonzero vector e (real or complex) such that $Ae = \lambda e$ for (real or complex) scalar λ ; this scalar is called the eigenvalue of A corresponding to the eigenvector e .

Eigenvalues of A are exactly the roots of the characteristic polynomial

$$\pi(z) = \det(zI - A) = z^n + b_1 z^{n-1} + b_2 z^{n-2} + \dots + b_n$$

of A .

Theorem C.2.1 states, in particular, that for a symmetric matrix A , all eigenvalues are real, and the corresponding eigenvectors can be chosen to be real and to form an orthonormal basis in \mathbf{R}^n .

C.2.B. Eigenvalue decomposition of a symmetric matrix. Theorem C.2.1 admits equivalent reformulation as follows (check the equivalence!):

Theorem C.2.2 An $n \times n$ matrix A is symmetric if and only if it can be represented in the form

$$A = U\Lambda U^T, \quad (\text{C.2.2})$$

where

- U is an orthogonal matrix: $U^{-1} = U^T$ (or, which is the same, $U^T U = I$, or, which is the same, $U U^T = I$, or, which is the same, the columns of U form an orthonormal basis in \mathbf{R}^n , or, which is the same, the columns of U form an orthonormal basis in \mathbf{R}^n).
- Λ is the diagonal matrix with the diagonal entries $\lambda_1, \dots, \lambda_n$.

Representation (C.2.2) with orthogonal U and diagonal Λ is called the eigenvalue decomposition of A . In such a representation,

- The columns of U form an orthonormal system of eigenvectors of A ;
- The diagonal entries in Λ are the eigenvalues of A corresponding to these eigenvectors.

C.2.C. Vector of eigenvalues. When speaking about eigenvalues $\lambda_i(A)$ of a symmetric $n \times n$ matrix A , we always arrange them in the non-ascending order:

$$\lambda_1(A) \geq \lambda_2(A) \geq \dots \geq \lambda_n(A);$$

$\lambda(A) \in \mathbf{R}^n$ denotes the vector of eigenvalues of A taken in the above order.

C.2.D. Freedom in eigenvalue decomposition. Part of the data Λ, U in the eigenvalue decomposition (C.2.2) is uniquely defined by A , while the other data admit certain “freedom”. Specifically, the sequence $\lambda_1, \dots, \lambda_n$ of eigenvalues of A (i.e., diagonal entries of Λ) is exactly the sequence of roots of the characteristic polynomial of A (every root is repeated according to its multiplicity) and thus is uniquely defined by A (provided that we arrange the entries of the sequence in the non-ascending order). The columns of U are not uniquely defined by A . What is uniquely defined, are the *linear spans* $E(\lambda)$ of the columns of U corresponding to all eigenvalues equal to certain λ ; such a linear span is nothing but the *spectral subspace* $\{x : Ax = \lambda x\}$ of A corresponding to the eigenvalue λ . There are as many spectral subspaces as many different eigenvalues; spectral subspaces corresponding to different eigenvalues of symmetric matrix are orthogonal to each other, and their sum is the entire space. When building an orthogonal matrix U in the spectral decomposition, one chooses an orthonormal eigenbasis in the spectral subspace corresponding to the largest eigenvalue and makes the vectors of this basis the first columns in U , then chooses an orthonormal basis in the spectral subspace corresponding to the second largest eigenvalue and makes the vector from this basis the next columns of U , and so on.

C.2.E. “Simultaneous” decomposition of commuting symmetric matrices. Let A_1, \dots, A_k be $n \times n$ symmetric matrices. It turns out that *the matrices commute with each other* ($A_i A_j = A_j A_i$ for all i, j) *if and only if they can be “simultaneously diagonalized”*, i.e., *there exist a single orthogonal matrix U and diagonal matrices $\Lambda_1, \dots, \Lambda_k$ such that*

$$A_i = U \Lambda_i U^T, \quad i = 1, \dots, k.$$

You are welcome to prove this statement by yourself; to simplify your task, here are two simple and important by their own right statements which help to reach your target:

C.2.E.1: *Let λ be a real and A, B be two commuting $n \times n$ matrices. Then the spectral subspace $E = \{x : Ax = \lambda x\}$ of A corresponding to λ is invariant for B (i.e., $Be \in E$ for every $e \in E$).*

C.2.E.2: *If A is an $n \times n$ matrix and L is an invariant subspace of A (i.e., L is a linear subspace such that $Ae \in L$ whenever $e \in L$), then the orthogonal complement L^\perp of L is invariant for the matrix A^T . In particular, if A is symmetric and L is invariant subspace of A , then L^\perp is invariant subspace of A as well.*

C.3 Variational Characterization of Eigenvalues

Theorem C.3.1 [VCE – Variational Characterization of Eigenvalues] *Let A be a symmetric matrix. Then*

$$\lambda_\ell(A) = \min_{E \in \mathcal{E}_\ell} \max_{x \in E, x^T x = 1} x^T A x, \quad \ell = 1, \dots, n, \quad (\text{C.3.1})$$

where \mathcal{E}_ℓ is the family of all linear subspaces in \mathbf{R}^n of the dimension $n - \ell + 1$.

VCE says that to get the largest eigenvalue $\lambda_1(A)$, you should maximize the quadratic form $x^T A x$ over the unit sphere $S = \{x \in \mathbf{R}^n : x^T x = 1\}$; the maximum is exactly $\lambda_1(A)$. To get the second largest eigenvalue $\lambda_2(A)$, you should act as follows: you choose a linear subspace E of dimension $n - 1$ and maximize the quadratic form $x^T A x$ over the cross-section of S by this

subspace; the maximum value of the form depends on E , and you minimize this maximum over linear subspaces E of the dimension $n - 1$; the result is exactly $\lambda_2(A)$. To get $\lambda_3(A)$, you replace in the latter construction subspaces of the dimension $n - 1$ by those of the dimension $n - 2$, and so on. In particular, the smallest eigenvalue $\lambda_n(A)$ is just the minimum, over all linear subspaces E of the dimension $n - n + 1 = 1$, i.e., over all lines passing through the origin, of the quantities $x^T Ax$, where $x \in E$ is unit ($x^T x = 1$); in other words, $\lambda_n(A)$ is just the minimum of the quadratic form $x^T Ax$ over the unit sphere S .

Proof of the VCE is pretty easy. Let e_1, \dots, e_n be an orthonormal eigenbasis of A : $Ae_\ell = \lambda_\ell(A)e_\ell$. For $1 \leq \ell \leq n$, let $F_\ell = \text{Lin}\{e_1, \dots, e_\ell\}$, $G_\ell = \text{Lin}\{e_\ell, e_{\ell+1}, \dots, e_n\}$. Finally, for $x \in \mathbf{R}^n$ let $\xi(x)$ be the vector of coordinates of x in the orthonormal basis e_1, \dots, e_n . Note that

$$x^T x = \xi^T(x) \xi(x),$$

since $\{e_1, \dots, e_n\}$ is an orthonormal basis, and that

$$\begin{aligned} x^T Ax &= x^T A \sum_i \xi_i(x) e_i = x^T \sum_i \lambda_i(A) \xi_i(x) e_i = \\ &= \sum_i \lambda_i(A) \xi_i(x) \underbrace{(x^T e_i)}_{\xi_i(x)} \\ &= \sum_i \lambda_i(A) \xi_i^2(x). \end{aligned} \tag{C.3.2}$$

Now, given ℓ , $1 \leq \ell \leq n$, let us set $E = G_\ell$; note that E is a linear subspace of the dimension $n - \ell + 1$. In view of (C.3.2), the maximum of the quadratic form $x^T Ax$ over the intersection of our E with the unit sphere is

$$\max \left\{ \sum_{i=\ell}^n \lambda_i(A) \xi_i^2 : \sum_{i=\ell}^n \xi_i^2 = 1 \right\},$$

and the latter quantity clearly equals to $\max_{\ell \leq i \leq n} \lambda_i(A) = \lambda_\ell(A)$. Thus, for appropriately chosen $E \in \mathcal{E}_\ell$, the inner maximum in the right hand side of (C.3.1) equals to $\lambda_\ell(A)$, whence the right hand side of (C.3.1) is $\leq \lambda_\ell(A)$. It remains to prove the opposite inequality. To this end, consider a linear subspace E of the dimension $n - \ell + 1$ and observe that it has nontrivial intersection with the linear subspace F_ℓ of the dimension ℓ (indeed, $\dim E + \dim F_\ell = (n - \ell + 1) + \ell > n$, so that $\dim(E \cap F) > 0$ by the Dimension formula). It follows that there exists a unit vector y belonging to both E and F_ℓ . Since y is a unit vector from F_ℓ , we have $y = \sum_{i=1}^{\ell} \eta_i e_i$ with $\sum_{i=1}^{\ell} \eta_i^2 = 1$, whence, by (C.3.2),

$$y^T Ay = \sum_{i=1}^{\ell} \lambda_i(A) \eta_i^2 \geq \min_{1 \leq i \leq \ell} \lambda_i(A) = \lambda_\ell(A).$$

Since y is in E , we conclude that

$$\max_{x \in E: x^T x = 1} x^T Ax \geq y^T Ay \geq \lambda_\ell(A).$$

Since E is an arbitrary subspace from \mathcal{E}_ℓ , we conclude that the right hand side in (C.3.1) is $\geq \lambda_\ell(A)$. ■

A simple and useful byproduct of our reasoning is the relation (C.3.2):

Corollary C.3.1 *For a symmetric matrix A , the quadratic form $x^T Ax$ is weighted sum of squares of the coordinates $\xi_i(x)$ of x taken with respect to an orthonormal eigenbasis of A ; the weights in this sum are exactly the eigenvalues of A :*

$$x^T Ax = \sum_i \lambda_i(A) \xi_i^2(x).$$

Corollaries of the VCE

VCE admits a number of extremely important corollaries as follows:

C.3.A. Eigenvalue characterization of positive (semi)definite matrices. Recall that a matrix A is called positive definite (notation: $A \succ 0$), if it is symmetric and the quadratic form $x^T A x$ is positive outside the origin; A is called positive semidefinite (notation: $A \succeq 0$), if A is symmetric and the quadratic form $x^T A x$ is nonnegative everywhere. VCE provides us with the following eigenvalue characterization of positive (semi)definite matrices:

Proposition C.3.1 : *A symmetric matrix A is positive semidefinite if and only if its eigenvalues are nonnegative; A is positive definite if and only if all eigenvalues of A are positive*

Indeed, A is positive definite, if and only if the minimum value of $x^T A x$ over the unit sphere is positive, and is positive semidefinite, if and only if this minimum value is nonnegative; it remains to note that by VCE, the minimum value of $x^T A x$ over the unit sphere is exactly the minimum eigenvalue of A .

C.3.B. \succeq -Monotonicity of the vector of eigenvalues. Let us write $A \succeq B$ ($A \succ B$) to express that A, B are symmetric matrices of the same size such that $A - B$ is positive semidefinite (respectively, positive definite).

Proposition C.3.2 *If $A \succeq B$, then $\lambda(A) \geq \lambda(B)$, and if $A \succ B$, then $\lambda(A) > \lambda(B)$.*

Indeed, when $A \succeq B$, then, of course,

$$\max_{x \in E: x^T x = 1} x^T A x \geq \max_{x \in E: x^T x = 1} x^T B x$$

for every linear subspace E , whence

$$\lambda_\ell(A) = \min_{E \in \mathcal{E}_\ell} \max_{x \in E: x^T x = 1} x^T A x \geq \min_{E \in \mathcal{E}_\ell} \max_{x \in E: x^T x = 1} x^T B x = \lambda_\ell(B), \quad \ell = 1, \dots, n,$$

i.e., $\lambda(A) \geq \lambda(B)$. The case of $A \succ B$ can be considered similarly.

C.3.C. Eigenvalue Interlacement Theorem. We shall formulate this extremely important theorem as follows:

Theorem C.3.2 [Eigenvalue Interlacement Theorem] *Let A be a symmetric $n \times n$ matrix and \bar{A} be the angular $(n-k) \times (n-k)$ submatrix of A . Then, for every $\ell \leq n-k$, the ℓ -th eigenvalue of \bar{A} separates the ℓ -th and the $(\ell+k)$ -th eigenvalues of A :*

$$\lambda_\ell(A) \succeq \lambda_\ell(\bar{A}) \succeq \lambda_{\ell+k}(A). \quad (\text{C.3.3})$$

Indeed, by VCE, $\lambda_\ell(\bar{A}) = \min_{E \in \bar{\mathcal{E}}_\ell} \max_{x \in E: x^T x = 1} x^T A x$, where $\bar{\mathcal{E}}_\ell$ is the family of all linear subspaces of the dimension $n-k-\ell+1$ contained in the linear subspace $\{x \in \mathbf{R}^n : x_{n-k+1} = x_{n-k+2} = \dots = x_n = 0\}$. Since $\bar{\mathcal{E}}_\ell \subset \mathcal{E}_{\ell+k}$, we have

$$\lambda_\ell(\bar{A}) = \min_{E \in \bar{\mathcal{E}}_\ell} \max_{x \in E: x^T x = 1} x^T A x \geq \min_{E \in \mathcal{E}_{\ell+k}} \max_{x \in E: x^T x = 1} x^T A x = \lambda_{\ell+k}(A).$$

We have proved the left inequality in (C.3.3). Applying this inequality to the matrix $-A$, we get

$$-\lambda_\ell(\bar{A}) = \lambda_{n-k-\ell}(-\bar{A}) \geq \lambda_{n-k-\ell}(-A) = -\lambda_{\ell+k}(A),$$

or, which is the same, $\lambda_\ell(\bar{A}) \leq \lambda_{\ell+k}(A)$, which is the first inequality in (C.3.3).

C.4 Positive Semidefinite Matrices and the Semidefinite Cone

C.4.A. Positive semidefinite matrices. Recall that an $n \times n$ matrix A is called *positive semidefinite* (notation: $A \succeq 0$), if A is symmetric and produces nonnegative quadratic form:

$$A \succeq 0 \Leftrightarrow \{A = A^T \quad \text{and} \quad x^T A x \geq 0 \quad \forall x\}.$$

A is called *positive definite* (notation: $A \succ 0$), if it is positive semidefinite and the corresponding quadratic form is positive outside the origin:

$$A \succ 0 \Leftrightarrow \{A = A^T \quad \text{and} \quad x^T A x > 0 \quad \forall x \neq 0\}.$$

It makes sense to list a number of equivalent definitions of a positive semidefinite matrix:

Theorem C.4.1 *Let A be a symmetric $n \times n$ matrix. Then the following properties of A are equivalent to each other:*

- (i) $A \succeq 0$
- (ii) $\lambda(A) \geq 0$
- (iii) $A = D^T D$ for certain rectangular matrix D
- (iv) $A = \Delta^T \Delta$ for certain upper triangular $n \times n$ matrix Δ
- (v) $A = B^2$ for certain symmetric matrix B ;
- (vi) $A = B^2$ for certain $B \succeq 0$.

The following properties of a symmetric matrix A also are equivalent to each other:

- (i') $A \succ 0$
- (ii') $\lambda(A) > 0$
- (iii') $A = D^T D$ for certain rectangular matrix D of rank n
- (iv') $A = \Delta^T \Delta$ for certain nondegenerate upper triangular $n \times n$ matrix Δ
- (v') $A = B^2$ for certain nondegenerate symmetric matrix B ;
- (vi') $A = B^2$ for certain $B \succ 0$.

Proof. (i) \Leftrightarrow (ii): this equivalence is stated by Proposition C.3.1.

(ii) \Leftrightarrow (vi): Let $A = U\Lambda U^T$ be the eigenvalue decomposition of A , so that U is orthogonal and Λ is diagonal with nonnegative diagonal entries $\lambda_i(A)$ (we are in the situation of (ii) !). Let $\Lambda^{1/2}$ be the diagonal matrix with the diagonal entries $\lambda_i^{1/2}(A)$; note that $(\Lambda^{1/2})^2 = \Lambda$. The matrix $B = U\Lambda^{1/2}U^T$ is symmetric with nonnegative eigenvalues $\lambda_i^{1/2}(A)$, so that $B \succeq 0$ by Proposition C.3.1, and

$$B^2 = U\Lambda^{1/2} \underbrace{U^T U}_I \Lambda^{1/2} U^T = U(\Lambda^{1/2})^2 U^T = U\Lambda U^T = A,$$

as required in (vi).

(vi) \Rightarrow (v): evident.

(v) \Rightarrow (iv): Let $A = B^2$ with certain symmetric B , and let b_i be i -th column of B . Applying the Gram-Schmidt orthogonalization process (see proof of Theorem A.2.3.(iii)), we can find an orthonormal system of vectors u_1, \dots, u_n and lower triangular matrix L such that $b_i = \sum_{j=1}^i L_{ij} u_j$, or, which is the same, $B^T = LU$, where U is the orthogonal matrix with the rows u_1^T, \dots, u_n^T . We now have $A = B^2 = B^T(B^T)^T = LUU^T L^T = LL^T$. We see that $A = \Delta^T \Delta$, where the matrix $\Delta = L^T$ is upper triangular.

(iv) \Rightarrow (iii): evident.

(iii) \Rightarrow (i): If $A = D^T D$, then $x^T A x = (Dx)^T (Dx) \geq 0$ for all x .

We have proved the equivalence of the properties (i) – (vi). Slightly modifying the reasoning (do it yourself!), one can prove the equivalence of the properties (i') – (vi'). ■

Remark C.4.1 (i) [Checking positive semidefiniteness] Given an $n \times n$ symmetric matrix A , one can check whether it is positive semidefinite by a purely algebraic finite algorithm (the so called *Lagrange diagonalization of a quadratic form*) which requires at most $O(n^3)$ arithmetic operations. Positive definiteness of a matrix can be checked also by the *Choleski factorization algorithm* which finds the decomposition in (iv'), if it exists, in approximately $\frac{1}{6}n^3$ arithmetic operations.

There exists another useful algebraic criterion (Sylvester's criterion) for positive semidefiniteness of a matrix; according to this criterion, a symmetric matrix A is positive definite if and only if its angular minors are positive, and A is positive semidefinite if and only if all its principal minors are nonnegative. For example, a symmetric 2×2 matrix $A = \begin{bmatrix} a & b \\ b & c \end{bmatrix}$ is positive semidefinite if and only if $a \geq 0$, $c \geq 0$ and $\det(A) \equiv ac - b^2 \geq 0$.

(ii) [Square root of a positive semidefinite matrix] By the first chain of equivalences in Theorem C.4.1, a symmetric matrix A is $\succeq 0$ if and only if A is the square of a positive semidefinite matrix B . The latter matrix is uniquely defined by $A \succeq 0$ and is called the *square root* of A (notation: $A^{1/2}$).

C.4.B. The semidefinite cone. When adding symmetric matrices and multiplying them by reals, we add, respectively multiply by reals, the corresponding quadratic forms. It follows that

C.4.B.1: *The sum of positive semidefinite matrices and a product of a positive semidefinite matrix and a nonnegative real is positive semidefinite,*

or, which is the same (see Section 2.1.4),

C.4.B.2: *$n \times n$ positive semidefinite matrices form a cone \mathbf{S}_+^n in the Euclidean space \mathbf{S}^n of symmetric $n \times n$ matrices, the Euclidean structure being given by the Frobenius inner product $\langle A, B \rangle = \text{Tr}(AB) = \sum_{i,j} A_{ij} B_{ij}$.*

The cone \mathbf{S}_+^n is called the *semidefinite cone* of size n . It is immediately seen that the semidefinite cone \mathbf{S}_+^n is “good,” specifically,

- \mathbf{S}_+^n is closed: the limit of a converging sequence of positive semidefinite matrices is positive semidefinite;
- \mathbf{S}_+^n is pointed: the only $n \times n$ matrix A such that both A and $-A$ are positive semidefinite is the zero $n \times n$ matrix;
- \mathbf{S}_+^n possesses a nonempty interior which is comprised of positive definite matrices.

Note that the relation $A \succeq B$ means exactly that $A - B \in \mathbf{S}_+^n$, while $A \succ B$ is equivalent to $A - B \in \text{int } \mathbf{S}_+^n$. The “matrix inequalities” $A \succeq B$ ($A \succ B$) match the standard properties of

the usual scalar inequalities, e.g.:

$$\begin{array}{ll}
A \succeq A & [\text{reflexivity}] \\
A \succeq B, B \succeq A \Rightarrow A = B & [\text{antisymmetry}] \\
A \succeq B, B \succeq C \Rightarrow A \succeq C & [\text{transitivity}] \\
A \succeq B, C \succeq D \Rightarrow A + C \succeq B + D & [\text{compatibility with linear operations, I}] \\
A \succeq B, \lambda \geq 0 \Rightarrow \lambda A \succeq \lambda B & [\text{compatibility with linear operations, II}] \\
A_i \succeq B_i, A_i \rightarrow A, B_i \rightarrow B \text{ as } i \rightarrow \infty \Rightarrow A \succeq B & [\text{closedness}]
\end{array}$$

with evident modifications when \succeq is replaced with \succ , or

$$A \succeq B, C \succ D \Rightarrow A + C \succ B + D,$$

etc. Along with these standard properties of inequalities, the inequality \succeq possesses a nice additional property:

C.4.B.3: *In a valid \succeq -inequality*

$$A \succeq B$$

one can multiply both sides from the left and by the right by a (rectangular) matrix and its transpose:

$$\begin{array}{c}
A, B \in \mathbf{S}^n, \quad A \succeq B, \quad V \in \mathbf{M}^{n,m} \\
\Downarrow \\
V^T A V \succeq V^T B V
\end{array}$$

Indeed, we should prove that if $A - B \succeq 0$, then also $V^T(A - B)V \succeq 0$, which is immediate – the quadratic form $y^T[V^T(A - B)V]y = (Vy)^T(A - B)(Vy)$ of y is nonnegative along with the quadratic form $x^T(A - B)x$ of x .

An important additional property of the semidefinite cone is its *self-duality*:

Theorem C.4.2 *A symmetric matrix Y has nonnegative Frobenius inner products with all positive semidefinite matrices if and only if Y itself is positive semidefinite.*

Proof. “if” part: Assume that $Y \succeq 0$, and let us prove that then $\text{Tr}(YX) \geq 0$ for every $X \succeq 0$. Indeed, the eigenvalue decomposition of Y can be written as

$$Y = \sum_{i=1}^n \lambda_i(Y) e_i e_i^T,$$

where e_i are the orthonormal eigenvectors of Y . We now have

$$\begin{aligned}
\text{Tr}(YX) &= \text{Tr}\left(\left(\sum_{i=1}^n \lambda_i(Y) e_i e_i^T\right)X\right) = \sum_{i=1}^n \lambda_i(Y) \text{Tr}(e_i e_i^T X) \\
&= \sum_{i=1}^n \lambda_i(Y) \text{Tr}(e_i^T X e_i),
\end{aligned} \tag{C.4.1}$$

where the concluding equality is given by the following well-known property of the trace:

C.4.B.4: *Whenever matrices A, B are such that the product AB makes sense and is a square matrix, one has*

$$\text{Tr}(AB) = \text{Tr}(BA).$$

Indeed, we should verify that if $A \in \mathbf{M}^{p,q}$ and $B \in \mathbf{M}^{q,p}$, then $\text{Tr}(AB) = \text{Tr}(BA)$. The left hand side quantity in our hypothetic equality is $\sum_{i=1}^p \sum_{j=1}^q A_{ij}B_{ji}$, and the right hand side quantity is $\sum_{j=1}^q \sum_{i=1}^p B_{ji}A_{ij}$; they indeed are equal.

Looking at the concluding quantity in (C.4.1), we see that it indeed is nonnegative whenever $X \succeq 0$ (since $Y \succeq 0$ and thus $\lambda_i(Y) \geq 0$ by P.7.5).

"only if" part: We are given Y such that $\text{Tr}(YX) \geq 0$ for all matrices $X \succeq 0$, and we should prove that $Y \succeq 0$. This is immediate: for every vector x , the matrix $X = xx^T$ is positive semidefinite (Theorem C.4.1.(iii)), so that $0 \leq \text{Tr}(Yxx^T) = \text{Tr}(x^TYx) = x^TYx$. Since the resulting inequality $x^TYx \geq 0$ is valid for every x , we have $Y \succeq 0$. ■
